(Dated: February 27, 2012)

Abstract

We present a direct measurement of the mass difference between t and $\bar{t}$ quarks using $t\bar{t}$ candidate events in the lepton+jets channel, collected with the CDF II detector at Fermilab's 1.96 TeV Tevatron $p\bar{p}$ Collider. We make an event by event estimate of the mass difference to construct templates for top quark pair signal events and background events. The resulting mass difference distribution of data is compared to templates of signals and background using a maximum likelihood fit. From a sample corresponding to an integrated luminosity of 8.7 fb^{-1}, which is the full data sample of Tevatron RunII, we measure a mass difference, $\Delta M_{\rm top} = M_t - M_{\bar{t}} = -1.95 \pm 1.11\,({\rm stat}) \pm 0.59\,({\rm syst})$ GeV/c^2. This is in agreement with the SM of no mass difference and the most precise measurement to date.

Preliminary Results of $\Delta{\rm M}_{top}$ using 8.7 fb^{-1}

The quantum field theory is invariant under CPT (charge, parity, and time reversal) transformations. CPT conservation is fundmental in the standard model (SM) providing most important constraints on the theory. However, it is important to examine the possibility of CPT violation in all sectors, as there are well-motivated extensions of the SM allowing for CPT symmetry breaking [1]. In the CPT theorem, particle and anti-particle masses must be identical; thus, a mass difference between particle and its anti-particle would indicate a violation of CPT. This issue has been tested of many elementary particles such as leptons and hadrons [2, 3], but not for quarks. Because of color charge carried by the quark, it is not observed directly but must hadronized into colorless particles, jets. With the exception of the top quark, direct measurement of quark masses are nearly impossible because hadronization time scale of quark is order of magnitude less than the decay time of quark and hadron masses yield, at best, only rough estimates of the quark mass. The top quark is by far the most massive quark and, with lifetime of the order of 10^{-24} seconds, decays before it can hadronize. This allows a precise measurement of the mass difference between t and $\bar{t}$ quarks and provides a probe of CPT violation in the quark sector [4].

Since top quark discovery in the Tevatron, large sample of $t\bar{t}$ events has been collected. This make precision measurements of the top quark mass (M_{top}) to an accurary of approximately 0.5% precision [5] of $M_{top} = 173.2 \pm 0.9$ GeV/c^2 using partial data of Tevatron RunII and even more precise measurements using total data samples [6]. Precision top quark mass measurements allowed to test the mass difference ($\Delta M_{top} = M_t - M_{\bar{t}}$) between t and $\bar{t}$ using similar technique with high precision. D0 collaboration had measurements of ΔM_{top} using matrix element method. The most recent result using 3.6 fb^{-1} data sample is good in agree with the SM of $\Delta M_{top} = 0.8 \pm 1.9$ GeV/c^2 [7]. CDF collaboration had a most precise measurement using 5.6 fb^{-1} in $p\bar{p}$ collisions [8] and measured $\Delta M_{top} = -3.3 \pm 1.7$ GeV/c^2 consistent within two standard deviation of the SM. This letter reports a new measurement of the ΔM_{top} using a full data sample of Tevatron RunII with $\sqrt{s} = 1.96$ TeV, collected with the CDF II detector [9]. This new measurement employs the same template method of previous CDF measurement using lepton+jets final state of $t\bar{t}$ production. This not only extends the data sample to the full data of RunII but also improves technique of jet energy calibration employed in the precision M_{top} measurement using same amout of the data at CDF [6]. We also re-examine the systematic uncertainties with larger statisitics of signal sample.

Assuming unitarity of the three-generation CKM matrix, t and $\bar{t}$ quarks decay almost exclusively into a W boson and a bottom quark ($t \to bW^+$ and $\bar{t} \to \bar{b}W^-$) [10]. The case where one W decays into a charged lepton and a neutrino ($W^+ \to \bar{\ell}\nu$ or $W^- \to \ell\bar{\nu}$) and the other into a pair of jets defines the lepton+jets decay channel. The electric charge of the lepton (-1 for ℓ and +1 for $\bar{\ell}$) determines the flavor of top quarks with event reconstruction. To select $t\bar{t}$ candidate events in this channel, we require one electron (muon) with $E_T > 20$ GeV ($p_T > 20$ GeV/c) and pseudorapidity $|\eta| < 1.1$ [11]. We also require high missing transverse energy [12], $\not{E}_T > 20$ GeV, and at least four jets. Jets are reconstructed with a cone algorithm [13] with radius $R = \sqrt{(\Delta\eta)^2 + (\Delta\phi)^2} = 0.4$. In addition to standard correction of jet energy [14] using the calorimeter information, we train the neural network incorporating jet energy from calorimeter with the other informations of jets including jet momentum from tracker as described in Ref. [15]. The additional information of the jets improve the resolution of the reconstructed variables of the ΔM_{top} measurement. Jets originating from b quarks are identified using a secondary vertex tagging algorithm [16]. In order to optimize the background reduction process and improve the statistical power of the events, we divide the sample of $t\bar{t}$ candidate events into sub-samples with zero (0-tag), one (1-tag), and two or more (2-tag) b-tagged jets.

For the 0-tag events, we require exactly four jets with transverse energy $E_T > 20$ GeV and $|\eta| < 2.0$. In case of 1-tag and 2-tag events, three jets are required to have $E_T > 20$ GeV and $|\eta| < 2.0$, and a fourth jet is required to have $E_T > 12$ GeV and $|\eta| < 2.4$, with no restriction on the total number of jets. To reject backgrounds in the 0-tag or 1-tag events, we require the scalar sum of transverse energies in the event, $H_T = E_T^{\text{lepton}} + \not{E}_T + \sum_{\text{four jets}} E_T^{\text{jet}}$, to be greater than 250 GeV. The samples of exactly four jets (tight samples) with $E_T > 20$ GeV and $|\eta| < 2.0$ are divided with the events requiring loosened fourth jets requirements and more than five jets events (loose samples) in the 1-tag and 2-tag events. We then have five sub-samples (0-tag, 1-tagL, 1-tagT, 2-tagL, and 2-tagT, where T and L denote Tight and Loose samples of jet requirement) based on b-tagging and jets requirement.

The primary sources of background events are W+jets and QCD multijet production. Contributions from Z+jets, diboson, and single top production are expected to be small. To estimate the contribution of each process, we use a combination of data and Monte Carlo (MC) based techniques described in Ref. [17]. For the Z+jets, diboson, and single top quark events, we normalized MC simulation events using their respective theoretical cross

3

TABLE I: Expected and observed numbers of signal and background events assuming $t\bar{t}$ production cross-section $\sigma_{t\bar{t}} = 7.4$ pb and $M_{top} = 172.5$ GeV/c^2.

sections. The QCD multijet background is estimated with a data-driven approach. We model W+jets background events using MC simulation but the overall rate is determined using data after subtracting the rate of all the other backgrounds and $t\bar{t}$. Table I shows the expected background composition and the expected number of $t\bar{t}$ events separated only in b-tagging.

We assume selected events to be $t\bar{t}$ events in the lepton+jets channel and reconstruct them to form estimators of ΔM_{top}, using a special purpose kinematic fitter, in which we modify the standard fitter [18] to allow a mass difference between t and $\bar{t}$. Measured four-vectors of jets and lepton are corrected for known effects [14], and resolutions are assigned. The unclustered transverse energy (U_T), which is the sum of all transverse energy in the calorimeter that is not associated with the primary lepton or one of the leading four jets, is used to calculate the neutrino transverse momentum. The longitudinal momentum of the neutrino is a free (unconstrained) parameter which is effectively determined by the constraint on the invariant mass of the leptonic W. We then define a kinematic fit χ^2 having a free

parameter dm_{reco},

$$
\begin{aligned}
\chi^2 \ = \ & \Sigma_{i=\ell,4jets}(p_T^{i,fit} - p_T^{i,meas})^2/\sigma_i^2 \\
& + \ \Sigma_{k=x,y}(U_{T_k}^{fit} - U_{T_k}^{meas})^2/\sigma_k^2 \\
& + \ (\mathrm{M}_{jj} - \mathrm{M}_W)^2/\Gamma_W^2 + (\mathrm{M}_{\ell\nu} - \mathrm{M}_W)^2/\Gamma_W^2 \\
& + \ \{\mathrm{M}_{bjj} - (\overline{\mathrm{M}}_{\mathrm{top}} + dm_{reco}/2)\}^2/\Gamma_t^2 \\
& + \ \{\mathrm{M}_{b\ell\nu} - (\overline{\mathrm{M}}_{\mathrm{top}} - dm_{reco}/2)\}^2/\Gamma_t^2,
\end{aligned}
\qquad (1)
$$

where dm_{reco}^{min}, the dm_{reco} value at the lowest χ^2, represents the reconstructed mass difference between the hadronic and leptonic top decay ($\mathrm{M}_{bjj} - \mathrm{M}_{b\ell\nu}$). In this χ^2 formulation, the first term constrains the p_T of the lepton and four leading jets to their measured values within their uncertainties (σ_i); the second term does the same for both transverse components x and y of the unclustered transverse energy. In the remaining four terms, the quantities $\mathrm{M}_{jj}, \mathrm{M}_{\ell\nu}, \mathrm{M}_{bjj}$, and $\mathrm{M}_{b\ell\nu}$ refer to the invariant masses of the four vector sum of the particles denoted in the subscripts. M_W and $\overline{\mathrm{M}}_{\mathrm{top}}$ are the masses of the W boson (80.4 GeV/c^2) [10] and the average of t and $\bar{t}$ quark masses (172.5 GeV/c^2), close to the current best experimental determination [19], respectively. Γ_W (2.1 GeV/c^2) and Γ_t (1.5 GeV/c^2) are the total widths of the W boson and the t quark [10]. We assume that the total widths of the t and $\bar{t}$ quarks are equal. Determining the reconstructed mass difference of t and $\bar{t}$, Δm_{reco}, requires the identification of the flavor (t versus $\bar{t}$), and this is done using the electric charge of the lepton (Q_{lepton}), defining $\Delta m_{\mathrm{reco}} = -Q_{lepton} \times dm_{reco}^{min}$.

The use of different detector components and the different resolutions of the measured values for jet, lepton, and unclustered energy, make the reconstructed mass distribution of hadronic top quarks differ from that of leptonic top quarks. Because the sign of Δm_{reco} depends on the lepton charge, Δm_{reco} distributions for the positive and negative lepton events are different. We divide the sample into six sub-samples, two samples with positively and negatively charged leptons for each of 0-tag, 1-tagL, 1-tagT, 2-tagL, and 2-tagT samples.

With the assumption that the leading four jets in the event come from the four final quarks at the hard scattering level, there are 12, 6, and 2 possible assignments of jets to quarks for 0 b-tag, 1 b-tag, and 2 b-tag respectively. The minimization of χ^2 is performed for each jet-to-parton assignment, and Δm_{reco} is taken from the assignment that yields the

lowest χ^2 (χ^2_{min}). Events with $\chi^2_{min} > 9.0$ ($\chi^2_{min} > 3.0$) are removed from the sample to reject poorly reconstructed events for b-tagged (zero b-tagged) events. To increase the statistical power of the measurement, we employ an additional observable $\Delta m^{(2)}_{\mathrm{reco}}$ from the assignment that yields the 2nd lowest χ^2. Although it has a poorer sensitivity, $\Delta m^{(2)}_{\mathrm{reco}}$ provides additional information on $\Delta \mathrm{M}_{\mathrm{top}}$ and improves the statistical uncertainty.

Using MADGRAPH [20], we generate $t\bar{t}$ signal samples with $\Delta \mathrm{M}_{\mathrm{top}}$ between -20 GeV/c^2 and 20 GeV/c^2 using almost 2 GeV/c^2 step size, where we take the average mass value of t and $\bar{t}$ to be $\overline{\mathrm{M}}_{\mathrm{top}} = 172.5$ GeV/c^2. Parton showering of the signal events is simulated with PYTHIA [21], and the CDF detector is simulated using a GEANT-based software package [22].

We estimate the probability density functions (p.d.f.s) of signal and background templates using the kernel density estimation (KDE) [23, 24]. For the $\Delta \mathrm{M}_{\mathrm{top}}$ measurement with two observables (Δm_{reco} and $\Delta m^{(2)}_{\mathrm{reco}}$), we use the two dimensional KDE that accounts for the correlation between them. First, at discrete values of $\Delta \mathrm{M}_{\mathrm{top}}$ from -20 GeV/c^2 to 20 GeV/c^2, we estimate the p.d.f.s for the observables from above-mentioned $t\bar{t}$ MC samples. We interpolate the MC distributions to find p.d.f.s for arbitrary values of $\Delta \mathrm{M}_{\mathrm{top}}$ using the local polynomial smoothing method [25]. We fit the signal and background p.d.f.s to the measured distributions of the observables in the data using an unbinned maximum likelihood fit [26], where we minimize the negative logarithm of the likelihood with MINUIT [27]. Likelihoods are built for each of six sub-samples separately, and an overall likelihood is then obtained by multiplying them together. We evaluate the statistical uncertainty on $\Delta \mathrm{M}_{\mathrm{top}}$ by searching for the points where the negative logarithm of the likelihood exceeds the minimum by 0.5. Refs. [23, 28] provide detailed information about this technique.

We test the fitting procedure using 3000 MC pseudo experiments (PEs) for each of 11 equally spaced $\Delta \mathrm{M}_{\mathrm{top}}$ values ranging from -10 GeV/c^2 to 10 GeV/c^2. The distributions of the average residual of measured $\Delta \mathrm{M}_{\mathrm{top}}$ (deviation from the input $\Delta \mathrm{M}_{\mathrm{top}}$) for simulated experiments is consistent with zero and the width of the pull (the ratio of the residual to the uncertainty reported by MINUIT) is consistent with unity.

We examine a variety of systematic effects that could change the measurement by comparing results from PEs in which we vary relevant systematic parameters within their uncertainties. All systematic uncertainties are summarized in Table II. The dominant source of systematic uncertainty is the signal modeling, which we estimate using PEs with events generated with MADGRAPH and PYTHIA. We also estimate a parton showering uncertainty

TABLE II: Summary of systematic uncertainties on ΔM_{top}.

Source	CDF II Preliminary 8.7 fb^{-1} Uncertainty (GeV/c^2)
Signal modeling	0.14
Parton showering	0.17
Next Leading Order	0.16
b and $\bar{b}$ jets asymmetry	0.38
Jet energy scale	0.07
Parton distribution functions	0.12
b-jet energy scale	0.05
Background shape	0.20
Gluon fusion fraction	0.05
Initial and final state radiation	0.10
Monte Carlo statistics	0.07
Lepton energy scale	0.06
Multiple hadron interaction	0.05
Color reconnection	0.23
Total systematic uncertainty	0.59

by applying different showering models (PYTHIA and HERWIG [29]) to a sample generated with ALPGEN [30]. We address a possible difference in the detector response between b and $\bar{b}$ jets by comparing data and MC simulation events [31]. The high order effects are estimated using MC@NLO. We add a systematic uncertainty due to multiple hadron interactions to account for the fact that the average number of interactions in our MC samples is not exactly equal to the number observed in the data. The jet energy scale (JES), the dominant uncertainty in most of the top quark mass measurements, is partially canceled in the measurement of the mass difference. Therefore JES contributes only a small uncertainty to this measurement. Other sources of systematic effects, including uncertainties in parton distribution functions, gluon radiation, background shape and normalization, lepton energy scale, and color reconnection [28, 32], give small contributions. The total systematic uncertainty of 0.59 GeV/c^2 is derived from a quadrature sum of the listed uncertainties.

The likelihood fit to the data returns a mass difference

$$\Delta M_{top} = -1.95 \pm 1.11 \text{ (stat)} \pm 0.59 \text{ (syst) GeV}/c^2$$
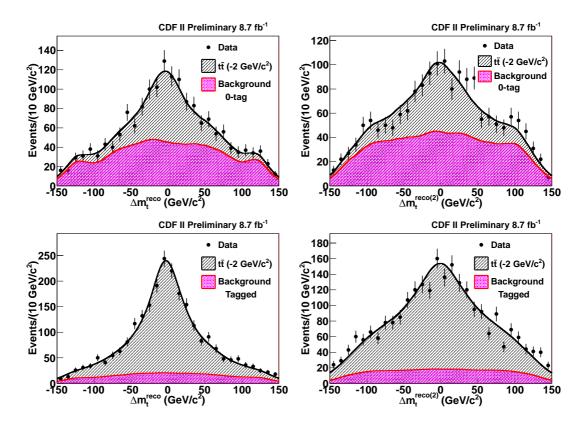

$$= -1.95 \pm 1.26 \text{ GeV}/c^2.$$

FIG. 1: (Color online) Distributions of Δm_{reco} and $\Delta m_{\text{reco}}^{(2)}$ used to extract ΔM_{top} for zero b-tagged (0-tag) events and one or more b-tagged (tagged) events. The data is overlaid with the predictions from the KDE probability distributions assuming $\Delta M_{\text{top}} = -2 \text{ GeV}/c^2$.

Figure 1 shows the measured distributions of the observables used for the ΔM_{top} measurement overlaid with density estimates using $t\bar{t}$ signal events with $\Delta M_{\text{top}} = -2 \text{ GeV}/c^2$ and the full background model.

In conclusion, we examine the mass difference between t and $\bar{t}$ quarks in the lepton+jets channel using data corresponding to an integrated luminosity of 8.7 fb^{-1} from $p\bar{p}$ collisions at $\sqrt{s} = 1.96$ TeV. We measure the mass difference to be $\Delta M_{\text{top}} = M_t - M_{\bar{t}} = -1.95 \pm 1.11 \text{ (stat)} \pm 0.59 \text{ (syst)} \text{ GeV}/c^2 = -1.95 \pm 1.26 \text{ GeV}/c^2$. This result is consistent with CPT-symmetry expectation, $\Delta M_{\text{top}} = 0 \text{ GeV}/c^2$. This is the most precise measurement of the mass difference between t and $\bar{t}$ quarks to date.

[11] We use a right-handed spherical coordinate system with the origin at the center of the detector. θ and ϕ are the polar and azimuthal angles, respectively. The pseudo-rapidity is defined by $\eta = -\ln\tan(\theta/2)$. The transverse momentum and energy are defined by $p_T = p\sin(\theta)$ and $E_T = E\sin(\theta)$, respectively, where p and E are the momentum and energy of the particle.

[12] The missing transverse energy, an imbalance of energy in the transverse plane of the detector, is defined by $\not{E}_T = -|\sum_{towers} E_T \hat{n}_T|$, where $\hat{n}_T$ is the unit vector normal to the beam and pointing to a given calorimeter tower and E_T is the transverse energy measured in that tower.

[31] We select a $b\bar{b}$ sample by requiring exactly two b-jets per event using a sample triggered on jet ($E_T > 20$ GeV). In addition, one b-jet is required to contain a soft muon from leptonic decays so that we can determine the charge of the b-quark associated with the jet. The energy scale of b and $\bar{b}$ jets in the data is compared with di-jet MC events to estimate the uncertainty of b and $\bar{b}$ jet energy scale independently. We perform PEs by varying the b and $\bar{b}$ energy separately within their uncertainties.
