Searches for New Physics in Photon Final States

Andrey Loginov
ITEP, Moscow

Received: date / Revised version: date

Abstract. The Run I results on the searches for new physics in photon final states were intriguing. The rare \( ee\gamma\gamma E_T \) candidate event and the measured event rate for the signature \( \ell + \gamma + E_T \), which was 2.7 sigma above the Standard Model predictions, sparked signature-based searches in the \( \gamma\gamma + X \) and \( \ell\gamma + X \) channels. With more data in Run II we should be able to answer a simple question: was it an anomaly or were the Run I results the first evidence for the new physics? We present searches for New Physics in Photon Final States at CDF Run II, Fermilab, with substantially more data and a higher \( pp \) collision energy, 1.96 TeV, and the upgraded CDF-II detector.

1 Introduction

The Standard Model is an effective field theory that has so far described the fundamental interactions of elementary particles [1] remarkably well. However the model breaks down at energies of a few TeV, in that the cross-section for scattering of longitudinal W bosons would otherwise violate unitarity. The Fermilab Tevatron has the highest center-of-mass energy collisions of any present accelerator, with \( \sqrt{s} = 1.96 \) TeV, and thus has the potential to discover new physics. As of September, 2005, the CDF experiment at Fermilab has recorded 1 \( fb^{-1} \) of data. Physics results using 202 \( pb^{-1} \) to 345 \( pb^{-1} \) are presented in this paper.

1.1 Motivation

Why do we consider the photon final states a good signature for observing new physics?

- Well Motivated Theories
  - Most importantly Supersymmetry
- History
  - Follow up on some of the anomalies from CDF in Run I [2-6]
  - From the experimentalists’ point of view, just because...
  - The photon is coupled to electric charge, and thus is radiated by all charged particles, including the incoming states (important for searching for invisible final states)

- The photon is massless and thus kinematically easier to produce than the W or Z

- The photon is stable, which implies a high acceptance, as there are no branching ratios to ‘pay’

- The photon is a boson and could be produced by a fermiphobic parent

- And if we then require
  - Additional Lepton(s) \( \Rightarrow \) high-\( E_T \) photon + high-\( P_T \) lepton + X signature is rare in SM, backgrounds are low for searches
  - Additional Photon(s) \( \Rightarrow \) the photons have moderate signal-to-noise but good efficiency and mass peak resolution

1.2 Run I Results

1.2.1 \( ee\gamma\gamma E_T \) Candidate Event

In 1995 the CDF experiment, measuring \( \bar{p}p \) collisions at a center-of-mass energy of 1.8 TeV at the Fermilab Tevatron, observed an event consistent with the production of two energetic photons, two energetic electrons, and large missing transverse energy [2,3,7](Figure 1).

This signature is predicted to be very rare in the Standard Model of particle physics, with the dominant contribution being from the \( WW\gamma\gamma \) production: \( WW\gamma\gamma \rightarrow (ev)(ev)\gamma\gamma \rightarrow ee\gamma\gamma E_T \), from which we expect \( 8 \times 10^{-7} \) events. All other sources (mostly detector misidentification) lead to \( 5 \times 10^{-7} \) events. Therefore, we expect \( (1 \pm 1) \times 10^{-6} \) events, which would give us one \( ee\gamma\gamma E_T \) candidate event if we have taken million times more data than we actually had in Run I.
1.2.2 $\gamma\gamma+X$ Search

The detection of this single event led to the development of ‘signature-based’ inclusive searches to cast a wider net: in this case one search for two photons + X [2, 3, 7], where X stands for anything, with the idea that if pairs of new particles were being created these inclusive signatures would be sensitive to a range of decay modes or the creation and decay of different particle types.

In Run I Searches for $\gamma\gamma+X$ all results were consistent with the Standard Model background expectations with no other exceptions other than observation of $ee\gamma E_T$ candidate event (Table 1) [3].

1.2.3 From $\gamma\gamma$ to $\ell\gamma X$ Search

Another ‘signature-based’ inclusive search, motivated by $ee\gamma E_T$ event was for one photon plus one lepton + X [5, 6, 9].

In general data agrees with expectations, with the exception for the $\ell\gamma E_T$ category. We have observed 16 $\ell\gamma E_T$ events on a background of $7.6 \pm 0.7$ expected. The 16 $\ell\gamma E_T$ events consist of 11 $\mu\gamma E_T$ events and 5 $e\gamma E_T$ events, versus expectations of $4.2 \pm 0.5$ and $3.4 \pm 0.3$ events, respectively. The SM prediction yields the observed rate of $\ell\gamma E_T$ with 0.7% probability (which is equivalent to 2.7 standard deviations for a Gaussian distribution).

One of the first SUSY interpretation of the CDF $\mu\gamma E_T$ events [10] was resonant smuon $\tilde{\mu}$ production with a single dominant R-parity violating coupling (Figure 2).

The Run I search was initiated by an anomaly in the data itself, and as such the 2.7 sigma excess above the Standard Model expectations must be viewed taking into account the number of such channels a fluctuation could have occurred in.

| Multi-Body $\ell\gamma E_T X$ | 5.8 ± 0.6 | 5 | 68.0 |
| Multi-Body $\ell\gamma E_T X$ | 0.02±0.02 | 1 | 1.5 |
| Multi-Body $\ell\gamma E_T X$ | 7.6 ± 0.7 | 16 | 0.7 |

### Fig. 1. The Run I $ee\gamma E_T$ Candidate Event

The event raised theoretical interest, however, as the two-lepton two-photon signature is expected in some models of physics ‘beyond the Standard Model’ [1] such as gauge-mediated models of supersymmetry [8]. For example, possible interpretation will be:

\[ p\bar{p} \rightarrow e^+e^- (+X)\]

\[ e \rightarrow \chi_0^0 + e, \chi_1^0 \rightarrow \chi_1^0 \gamma \]

where $e$ is the electron (the bosonic partner of the electron), and $\chi_0^0$ and $\chi_1^0$ are the lightest and next-to-lightest neutralinos.

| Category | $\mu_{SM}$ | $N_0$ | $P(N \geq N_0|\mu_{SM})$ |
|----------|------------|-------|--------------------------|

| Z-like $e\gamma$ | – | 17 | – |
| Two-Body $\ell\gamma X$ | 24.9±2.4 | 33 | 9.3 |
| Multi-Body $\ell\gamma X$ | 20.2±1.7 | 27 | 10.0 |
| Multi-Body $\ell\gamma E_T X$ | 5.8 ± 0.6 | 5 | 68.0 |
| Multi-Body $\ell\gamma E_T X$ | 0.02±0.02 | 1 | 1.5 |
| Multi-Body $\ell\gamma E_T X$ | 7.6 ± 0.7 | 16 | 0.7 |

### Fig. 2. Resonant smuon production and subsequent decay, producing the $\mu\gamma E_T$ signature

The Run I search was initiated by an anomaly in the data itself, and as such the 2.7 sigma excess above the Standard Model expectations must be viewed taking into account the number of such channels a fluctuation could have occurred in.

2 From Run I to Run II

Having many different hints from the signature-based searches for new physics in photon final states in Run I, the strategy for Run II was straightforward: take more data. The main points were:

- Increase the Collision Energy: 1.80 → 1.96 TeV
– Increase the rate at which we take data: 3500 → 396 ns (timing between bunches)
– Upgrade the Detectors

2.1 CDF Run II Detector

The CDF-II detector [11] is a cylindrically symmetric spectrometer designed to study \( pp \) collisions at the Fermilab Tevatron, that uses the same solenoidal magnet and central calorimeters as the CDF-I detector [12] from which it was upgraded. Because the analyses described here have been motivated by the Run I searches, we note especially the differences from the Run I detector relevant to the detection of photons, leptons, and \( E_T \).

The central calorimeters are physically unchanged; however, the readout electronics has been replaced to accommodate the smaller proton and anti-proton bunch spacing of the Tevatron in Run II. The end-cap (plug) and forward calorimeters have been replaced with a more compact scintillator-based design, retaining the projective geometry [13].

The tracking system used to measure the momenta of charged particles has been replaced, with the central outer tracker upgraded to have smaller drift cells [14], and the inner tracking chamber and silicon system replaced by a system of silicon strip chambers with more layers, now in 2-dimensions [15]. The new inner tracking system has substantially more material, resulting in more bremsstrahlung (photons) produced by high-\( P_T \) electrons.

The central CMU, CMP, and CMX muon systems are also physically unchanged in design, but the coverage of the CMP and CMX muon systems has been extended by filling in some gaps [16].

3 Run II: Searches for New Physics in Photon Final States

The Run I results on searches for new physics in photon final states were intriguing [2,3,5,6]. The rare \( ee \gamma \gamma E_T \) candidate event and the measured event rate for the signature \( \ell \gamma \gamma \) [19], which was 2.7 sigma above the Standard Model predictions, sparked signature-based searches in the \( \gamma \gamma + X \) and \( \ell \gamma + X \) channels.

With more data in Run II we should be able to answer a simple question: was it an anomaly or were the Run I results the first evidence for the new physics?

There are lots of searches involving photon final states at CDF in Run II. Some of the analyses are presented here:

– Search for High-Mass Diphoton State and Limits on Randall-Sundrum Gravitons (Section 3.1)
– Search for Anomalous Production of Diphoton Events with \( E_T \) and Limits on GMSB Models (Section 3.2)
– Search for Lepton-Photon-X Events (Section 3.3)

3.1 Search for High-Mass Diphoton State and Limits on Randall-Sundrum Gravitons

Searches for new particles decaying to two identical particles are broad, inclusive and sensitive. The production of the new particle may be direct or with associated particles, or in a decay chain. The discovery of a sharp mass peak over background would be compelling evidence of a new particle. The diphoton final state is important because the photons are bosons and the parent may be fermiphobic. The photons have moderate signal-to-noise but good efficiency and mass peak resolution.

One model producing a diphoton mass peak is Randall-Sundrum gravitons [17]. Current string theory proposes that as many as seven new dimensions may exist and the geometry of these extra dimensions is responsible for why the gravity is so weak. The Randall-Sundrum model [17] has the property that a parameter, the warp factor, determines the curvature of the extra dimensions and therefore the mass of the Kaluza-Klein graviton resonances, which decay to two bodies including photons.

Details on this analysis are available elsewhere [18].

3.1.1 Data Sample

Our sample corresponds to \( 345 \, pb^{-1} \) of data taken between February 2002 and July, 2004. We require that the data were taken under good detector conditions for the photon identification. We apply selection cuts as follows:

– Photons in Central Calorimeter
– \( E_T^\gamma > 15 \, GeV \)
– \( M(\gamma,\gamma) > 30 \, GeV \)

To select a photon in a central calorimeter (approximately \( 0.05 < |\eta| < 1.0 \)), we require a central electromagnetic cluster that: a) is not near the boundary in \( \phi \) of a calorimeter tower [19]; b) have the ratio of hadronic to electromagnetic energy, \( Had/EM, < 0.055 + 0.00045 \cdot E^\gamma(\text{GeV}^{-1}) \); c) have no tracks, or only one track with \( p_T < 1 \, GeV/c \), extrapolating to the towers of the cluster; d) is isolated in the calorimeter and tracking chamber [20]; e) have a shower shape in the CES consistent with a single photon; f) have no other significant energy deposited nearby in the CES.

The final dataset consists of 3339 events, for which the data histogrammed with bins equivalent to one \( \sigma \) of resolution are shown at Figure 3. The highest mass events occur at masses of 207, 247, 304, 329, and 405 GeV(Figure 4).

3.1.2 Backgrounds

There are two significant backgrounds to our sample. The first is SM diphoton production which accounts for 30% of the events(Figure 5). This background is estimated using a NLO Monte Carlo, diphox [21], which we normalize to \( \mathcal{L}=345 \, pb^{-1} \).
The diphoton mass distribution histogrammed in bins of approximately one \( \sigma \) of mass resolution.

The second background is jets, which are usually high-\( E_T \) \( \pi^0 \)'s. For a control sample, we loosen several cuts including relaxing the isolation cuts by 50\%, and we get 9891 events, from which we then reject events in the signal sample and are left with 6552 events in the “photon sideband” sample. We then derive the shape in the mass distribution by fitting this sample to a sum of several exponentials. We then subtract the estimate from the SM contribution and normalize the fakes background to the low mass (\( m_{\gamma\gamma} \) between 30 and 100 GeV).

Figure 6 shows the data mass spectrum compared to the prediction.

3.1.3 Limits on Randall-Sundrum Gravitons

Since the data are consistent with the SM prediction, we place upper limits on the cross sections times branching ratio of Randall-Sundrum graviton production and decay to diphotons (Figure 7).

Figure 8 shows the combined 95\% confidence level RS graviton mass limits of the di-photon (\( \mathcal{L} = 345 \text{ pb}^{-1} \)) and di-lepton (\( \mathcal{L} = 200 \text{ pb}^{-1} \)) searches [22] in the graviton mass versus coupling, \( k/M_{\text{Planck}} \), plane. Note, that \( \gamma\gamma \) has larger Branching Ratio (\( \text{Br}(G \rightarrow \gamma\gamma) = 2 \times \text{Br}(G \rightarrow ee) \)) and \( \gamma\gamma \) spin factors improve acceptance.
properties of the next-to-lightest SUSY particle (NLSP) that may be, for example, a slepton or the lightest neutralino (LSP) that is assumed to be stable, and the SUSY particles have masses that may make them accessible at Tevatron energies [23]. In these models the visible signatures are determined by the properties of the next-to-lightest SUSY particle (NLSP) that may be, for example, a slepton or the lightest neutralino ($\tilde{\chi}_1^0$). In the GMSB model investigated here, the NLSP is a $\tilde{\chi}_1^0$ decaying almost exclusively to a photon and a $G$ that penetrates the detector without interacting, producing $E_T$. SUSY particle production at the Tevatron is expected, due mostly to energy measurement resolution effects.

Beam-related sources and cosmic rays overlapped with a SM event can contribute to the background by producing spurious energy deposits that in turn affect the measured $E_T$. While the rate at which these events contribute to the diphoton candidate sample is low, most contain large $E_T$'s, leading to a final state of $\gamma\gamma + E_T + X$, where $X$ represents any other final state particles.

Details on this analysis are available elsewhere [25,26].

3.2 Search for Anomalous Production of Diphoton Events with $E_T$ and Limits on GMSB Models

For theoretical reasons [23,24], and because of the $ee\gamma E_T$ candidate event (Figure 1) recorded by the CDF detector in Run 1 [2,3], we want to search for the production of heavy new particles that decay producing the signature of $\gamma\gamma + E_T$. Of particular theoretical interest are supersymmetric (SUSY) models with gauge-mediated SUSY-breaking (GMSB). Characteristically, the effective SUSY-breaking scale ($\Lambda$) can be as low as 100 TeV, the lightest SUSY particle is a light gravitino ($\tilde{G}$) that is assumed to be stable, and the SUSY particles have masses that may make them accessible at Tevatron energies [23]. In these models the visible signatures are determined by the properties of the next-to-lightest SUSY particle (NLSP) that may be, for example, a slepton or the lightest neutralino ($\tilde{\chi}_1^0$). In the GMSB model investigated here, the NLSP is a $\tilde{\chi}_1^0$ decaying almost exclusively to a photon and a $G$ that penetrates the detector without interacting, producing $E_T$. SUSY particle production at the Tevatron is predicted to be dominated by pairs of the lightest chargino ($\tilde{\chi}^{\pm}$) and by associated production of a $\tilde{\chi}_1^0$ and the next-to-lightest neutralino ($\tilde{\chi}_2^0$). Each gaugino pair cascades down to two $\tilde{\chi}_1^0$'s, leading to a final state of $\gamma\gamma + E_T + X$, where $X$ represents any other final state particles.

3.2.2 Backgrounds

Backgrounds for our analysis are:

- QCD background: fake photon (jj, $j\gamma$)
- QCD background: $\gamma\gamma$
- $e\gamma$
- Non-Collision: beam-related, cosmic rays

Events with an electron and a photon candidate ($W\gamma \rightarrow e\nu\gamma$, $Wj \rightarrow j\nu\gamma$, $Z\gamma \rightarrow ee\gamma$, etc.) can contribute to the diphoton candidate sample when the electron track is lost (by tracking inefficiency or bremsstrahlung) to create a fake photon. For $W$ decays large $E_T$ can come from the neutrinos. This background is estimated using $e\gamma$ events from the data.

3.2.3 Limits on GMSB Models

No excess is observed in two photons + energy imbalance. The $E_T$ spectrum for events with two isolated central photons with $E_T^\gamma > 13$ GeV along with the predictions from the GMSB model is shown at Figure 9.

Since there is no evidence for events with anomalous $E_T$ in the diphoton candidate sample, we set limits on new particle production from GMSB using the parameters suggested in Ref. [27]. Using the NLO predictions we set a limit of $M_{\chi_\pm}^\gamma$, and then from mass relations in the model, we equivalently set limits on $M_{\chi_1^0}$ and $\Lambda$:

$M_{\chi_\pm}^\gamma > 167 \text{ GeV}/c^2$, $M_{\chi_0} > 93 \text{ GeV}/c^2$, $\Lambda > 69 \text{ GeV}/c^2$

Combined CDF+DØ limit [26] is significantly larger than either experiment alone [25,28]. The details on the combination of the results on the CDF and DØ searches for chargino and neutralino production in GMSB SUSY using the two-photon and missing $E_T$ channel are explained in [26].

Figure 10 shows the combined CDF and DØ result for the observed cross section [26] as a function of $M_{\chi_\pm}^\gamma$ and $M_{\chi_0}$ along with the theoretical LO and NLO production cross sections.
The combined CDF+DØ limits are: 

\( M_{\chi_1^\pm} > 209 \text{ GeV/c}^2, M_{\chi_1^0} > 114 \text{ GeV/c}^2, \Lambda > 84.6 \text{ GeV/c}^2 \) at 95% C.L. in GMSB Model. This is a first combined Run II result and it sets the world’s most stringent limits on the GMSB SUSY.

### 3.3 Search for Lepton-Photon-X Events

In Run I lepton+photon+X search the results were consistent with standard model expectations in a number of channels with “the possible exception of photon-lepton events with large \( E_T \), for which the observed total was 16 events and the Standard Model expectation was 7.6 ± 0.7 events, corresponding in likelihood to a 2.7 sigma effect.” [6]. We concluded “However, an excess of events with 0.7% likelihood (equivalent to 2.7 standard deviations for a Gaussian distribution) in one subsample among the five studied is an interesting result, but it is not a compelling observation of new physics. We look forward to more data in the upcoming run of the Fermilab Tevatron.” [6]. In this section we report the preliminary results [29] of repeating the \( e\gamma X \) search with the same kinematic selection criteria with a substantially larger data set, \( \mathcal{L} = 307 \text{ pb}^{-1} \), and a higher \( \bar{p}p \) collision energy, 1.96 TeV, and the upgraded CDF-II detector.

### 3.4 Data Sample

The data presented here were taken between March 21, 2002, and August 22, 2004 and represent 307 pb\(^{-1}\) for which the silicon detector [15] and all three central muon systems(CMP, CMU and CMX) [16] were operational.
Events with a high-transverse momentum ($P_T$) [30] photon or lepton are selected by a three-level trigger [31] that requires an event to have either a high-$E_T$ photon or a high-$P_T$ lepton ($e$ or $\mu$) within the central region, $|\eta| < 1.0$ [32]. Photon and electron candidates are chosen from clusters of energy in adjacent CEM towers; electrons are then further separated from photons by requiring the presence of a COT track pointing at the cluster. Muons are identified by requiring COT tracks to extrapolate to a reconstructed track segment in the muon drift chambers.

We have reused the Run I selection kinematic cuts for Run II analysis, so that they are a priori:

- Tight Muons: $P_T > 25$ GeV
- Tight Central Electrons, Photons: $E_T > 25$ GeV
- Loose Muons: $P_T > 20$ GeV
- Loose Central Electrons: $E_T > 20$ GeV
- Loose Plug Electrons: $E_T > 15$ GeV
- $E_T > 25$ GeV

The identification of photons is essentially the same as for other Run II searches for new physics in photon final states (Section 3.1.1).

The identification of leptons is essentially the same as in the Run I search [5], with only minor technical differences, most due to the changes in the construction of the tracking system and end-plug calorimeters.

A muon passing the ‘tight’ cuts is required to: a) have a track in the COT that passes quality cuts on the minimum number of hits on the track; b) deposit energy in the electromagnetic and hadronic compartments of the calorimeter consistent with that expected from a muon, c) match a muon ‘stub’ track in the CMX detector or in both the CMU and CMUP detectors [16]; d) not be a cosmic ray (determined from measuring timing with the COT).

Tight central electrons are required to have a high-quality track with $P_T$ of at least half the shower energy [33], minimal leakage into the hadronic calorimeter [34], a good profile in the $z$ dimension (the dimension in which the electron track is not bent by the magnetic field) at shower maximum that matches the extrapolated track position, and a lateral sharing of energy in the two calorimeter towers containing the electron shower consistent with that expected.

‘Loose’ central electrons and muons satisfy somewhat looser cuts [35,36]. ‘Loose’ electrons in the end-plug calorimeters are required to have $E_T > 15$ GeV, minimal leakage into the hadron calorimeters [34], a ‘track’ containing at least 3 hits in the silicon inner tracking system, and a shower transverse shape consistent with that expected, with a centroid close to the extrapolated position of the track.

Missing transverse energy, $E_T$, is calculated from the calorimeter tower energies in the region $\eta < 3.6$. Corrections are then made for jets, and for muons.

### 3.5 Control Samples and Backgrounds

We use $W$ and $Z^0$ production as control samples to ensure that the efficiencies for high-$P_T$ electrons and muons, as well as for $E_T$, are well understood. The photon control sample is constructed from $Z^0 \rightarrow e^+e^-$ decays in which one of the electrons radiates a hard photon, leading to an apparent process of $Z^0 \rightarrow e\gamma$.

The dominant source of photon-lepton events at the Tevatron is electroweak diboson production(Figure 11), in which a $W$ or $Z^0$ boson decays leptonically ($\ell\nu$ or $\ell\ell$) and a photon is radiated from either an initial-state quark, the $W$ or $Z^0$, or from a charged final-state lepton. The number of such events is estimated using leading-order (LO) matrix element event generators [37–39].

To simulate the triboson channels $W\gamma\gamma$ and $Z\gamma\gamma$ we have used MadGraph [37] and CompHep[39].

### 3.6 Lepton-Photon-X Results

Following the Run I analysis strategy, we define the $\ell\gamma E_T$ subsample by requiring that an event contain, in addition to the central lepton and central photon, $E_T > 25$ GeV. A second signal subsample, the $\ell\ell\gamma$ sample, is constructed by requiring, in addition to the central lepton and central photon, a second ‘loose’ lepton with $E_T > 25$ GeV. These two subsamples were selected as the search regions of interest from the Run I results with the same kinematic selections; these two searches in the Run II data are thus a priori. Both sample selections are ‘inclusive’, in that there are no requirements on the presence or absence of other objects.

In addition to the expectations from real SM processes that produce real lepton-photon events, there are backgrounds due to misidentified leptons and photons, and also incorrectly calculated $E_T$.

We consider two sources of fake photons: QCD jets in which a $\pi^0$ or photon from hadron decay mimics a direct photon, and electron bremsstrahlung, in which an energetic photon is radiated off of an electron which is then much lower energy and curls away from the photon.

Backgrounds from fake leptons and/or fake missing $E_T$ (‘QCD’) we estimate from a sample, in which we expect
to have very little real lepton content [40] by selecting on loose leptons, rejecting events from the W or Z.

Table 4. A comparison of the numbers of events predicted by the Standard Model and the observations for the \( \ell \gamma E_T \) and \( \ell \ell \gamma \) searches. The SM predictions for the two searches are dominated by W\( \gamma \) and Z\( \gamma \) production, respectively [37–39]. Other contributions come from the tri-boson processes W\( \gamma \gamma \), leptonic \( \tau \) decays, and misidentified leptons, photons, or \( E_T \).

Fig. 12. The distributions for events in the \( e\gamma E_T \) sample in a) the \( E_T \) of the photon; b) the \( E_T \) of the electron, c) the missing transverse energy, \( E_T \), and d) the transverse mass of the electron-photon-\( E_T \) system. The data are shown as solid circles. The histograms show the expected SM contributions, including estimated backgrounds from misidentified photons and leptons.

Fig. 13. The distributions for events in the \( \mu\gamma E_T \) sample in a) the \( E_T \) of the photon; b) the \( E_T \) of the muon, c) the missing transverse energy, \( E_T \), and d) the transverse mass of the muon-photon-\( E_T \) system. The data are shown as solid circles. The histograms show the expected SM contributions, including estimated backgrounds from misidentified photons and leptons.

The predicted and observed totals for both the \( e\gamma E_T \) and \( \ell\ell \gamma \) searches are shown in Table 4. We observe 43 \( e\gamma E_T \) events, versus the expectation of 35.1 ± 5.3 events. If the Run I ratio of observed to expected, which was 16/9, had held up, the 2.7 \( \sigma \) excess observed in Run I would have resulted in an observation of 62 events in the Run II repeat of the analysis, versus the 43 observed events. In the \( \ell\ell \gamma \) channel, we observe 31 events, versus an expectation of 21.2 ± 4.0 events.

While the number of events observed is somewhat larger than expectations (Table 4), there is not a significant excess in either signature, and the kinematic distributions are in reasonable agreement with the SM predicted shapes.

The distributions for events in the \( e\gamma E_T \) sample are shown at Figure 12 for the electron channel and Figure 13 for the muon channel. The dominant contribution for \( e\gamma E_T \) is Standard Model Z\( \gamma \) and W\( \gamma \) production.

The distributions for events in the \( \ell\ell \gamma \) sample are shown at Figure 14 for electron channel and Figure 15 for muon channel. The dominant contribution for \( \ell\ell \gamma \) is Standard Model Z\( \gamma \) production.

For the Z\( \gamma \) process occurring via initial state radiation, the dilepton invariant mass distribution will be peaked around the Z\( ^0 \)-pole. For the final state radiation, the three body invariant mass (m(\( l, l, \gamma \))) distribution will be peaked about the Z\( ^0 \)-pole (Figures 14, 15, (c) and (d)).

We do not expect missing \( E_T \) in the events in the \( \ell\ell \gamma \) sample based on the SM backgrounds; the \( ee\gamma E_T \) event was of especial interest due to the large value of \( E_T \). Figure 16 shows the distributions in \( E_T \) for the ee\( \gamma \) and \( \mu\mu\gamma \) channel.
In conclusion, we have repeated the search for inclusive photon+lepton production with the same kinematic requirements as the Run I search, but with a significantly larger data sample and a higher collision energy. We find that the $\ell\gamma E_T$ and $\ell\ell\gamma$ subsamples of this data set agree well with the SM predictions in number and in the shapes of kinematic distributions. We observe no further $\ell\ell\gamma$ events with anomalous large $E_T$, or with multiple photons, such as the $ee\gamma E_T$ event of Run I.

4 Summary and Outlook

To summarize, we will list the main points for the Run II results presented:

- Search for $\ell\gamma X$: The Run I 2.7 sigma excess in $\ell\gamma E_T$ is not confirmed in an exact repeat of the analysis with much more data (307 pb vs 86, 1.96 TeV vs 1.8 TeV).
- Search for $\gamma\gamma E_T + X$: No excess in two photons + energy imbalance. Combined CDF and DØ Result: world’s most stringent limits on GMSB SUSY. No new $ee\gamma E_T$ (or similar) candidate events found.
- Search for high-mass diphotons: the data agree with predictions. However, the photon signature is promising.

Photon searches at CDF are underway: CDF is taking data, which we analyze with “model independent” search techniques. A recent upgrade, the EM Timing system [41], provides a vitally important handle that could confirm or deny that all the photons in unusual events are from the primary collision.

Currently, the CDF is actively pursuing topics and analyzing up to 1 $fb^{-1}$ of delivered luminosity. New and exciting results are coming out quickly. Further information regarding the analyses presented in this paper and new results can be found at [42].

19. The fiducial region has ~87% coverage in the central region.
20. To reject hadronic backgrounds that fake prompt photons, candidates are required to be isolated in the calorimeter and tracking chamber. In the calorimeter the isolation is defined as the energy in a cone of 0.4 in \( \eta - \phi \) space, minus the photon cluster energy, and corrected for energy loss into cracks as well as the number of reconstructed \( \bar{p}p \) interactions in the event. We require isolation < 0.1 \( E_T^{\text{gamma}} < 20 \text{ GeV} \), and < 2.0 GeV+0.02 \( E_T^{\text{gamma}} > 20 \text{ GeV} \) for \( E_T^{\gamma} > 20 \text{ GeV} \). In the tracking chamber we require the scalar sum of the \( p_T \) of all tracks in a cone of 0.4 to be < 2.0 GeV+0.005 \( E_T^{\gamma} \), where all values of \( E_T^{\gamma} \) are in GeV.

22. High Mass Dielectrons:
   High Mass Dimuons:
26. V. Buescher, R. Culbertson et al., for the CDF and DØ collaborations hep/ex 0504004
27. B. C. Allanach et al., Eur. Phys. J. C25 113 (2002). We take the messenger mass scale \( M_M = 2 \Lambda \), \( \tan(\beta) = 15 \), \( \text{sign}(\mu) = 1 \), the number of messenger fields \( N_M = 1 \), and negligibly short \( \tilde{\chi}^0 \) lifetimes.
30. The transverse momentum is defined as \( p_T = p \sin \theta \); the transverse energy is defined as \( E_T = E \sin \theta \). Missing transverse energy is defined as \( E_T = -\sum E_T \), where the sum is over all objects in an event. We use the same convention as in the Run I analysis: ‘momentum’ refers to \( p_c \) and ‘mass’ to \( m_c^2 \), so that energy, momentum, and mass are all measured in GeV.
32. The CDF coordinate system of \( r, \varphi, \) and \( z \) is cylindrical, with the \( z \)-axis along the proton beam. The pseudorapidity is \( \eta = -\ln(\tan(\theta/2)) \).
33. The \( p_T \) cut is raised to 25 GeV for \( E_T > 100 \text{ GeV} \).
34. The fraction of electromagnetic energy \( E_{\text{em}} \) allowed to leak into the hadronic compartment is 0.055 + 0.00045\( E_{\text{em}} \) for tight and loose central electrons; for loose plug electrons and for photons the fraction must be less than 0.125.
35. Relaxed track quality cuts or no matching 'stub' in the muon systems [43]
36. Relaxed track requirements and no requirement on a shower maximum measurement or lateral energy sharing.
41. “The Timing System for the CDF Electromagnetic Calorimeters”, M. Goncharov et al., in preparation, to be submitted to NIM
42. See http://www-cdf.fnal.gov/physics/exotic/exotic.html
43. For tight muons and tight electrons we require at least 5 hits in each of 3 axial and 3 stereo layers of the COT; for loose muons with a matching muon stub this is relaxed to 3 axial and 2 stereo. Loose muons without a matching stub have an additional cut on the \( \chi^2 \) for the fit to the track.
