5 (Dated: February 17, 2014)

Abstract

We report on a study of the dijet invariant-mass distribution in events with one identified lepton, a significant imbalance in the total event transverse momentum, and two jets. This distribution is sensitive to the possible production of a new particle in association with a W boson, where the boson decays leptonically. We use the full data set of proton-antiproton collisions at 1.96 TeV center-of-mass energy collected by the Collider Detector at the Fermilab Tevatron and corresponding to an integrated luminosity of 8.9 fb^{-1} . The data are found to be consistent with standard-model expectations, and a 95% confidence level upper limit is set on the cross section for a W boson produced in association with a new particle decaying into two jets.

7 I. INTRODUCTION

8 At hadron colliders the production of jets in association with vector bosons allows for
9 precision tests of combined electroweak and quantum-chromodynamic (QCD) theoretical
10 predictions. Many extensions of the standard model (SM) predict significant deviations from
11 the SM predictions of the observable phenomena associated with these processes [1, 2, 3].
12 In a previous publication, we reported a disagreement between data and SM expectations
13 in a data sample corresponding to 4.3 fb^{-1} [4]. This disagreement appeared as an excess of
14 events in the $120\text{-}160 \text{ GeV}/c^2$ invariant-mass range of the jet pairs (M_{jj}) for events selected
15 by requiring one identified lepton, an imbalance in the total event transverse momentum, and
16 two jets. Assuming that the excess of events over the SM prediction was due to an unknown
17 contribution, modeled as a Gaussian resonance with width compatible with the expected
18 dijet-mass resolution, the statistical significance of the excess was 3.2 standard deviations.
19 Similar searches carried out by the DØ [5], CMS [6], and ATLAS [7] collaborations did
20 not confirm the CDF result in events with the same topology. Another search for a dijet
21 resonance carried out by the CDF collaboration in events with large missing transverse
22 energy and two or three jets observed good agreement between data and SM expectations [8].

23 In this paper, we report on an update of the previous analysis [4] using the full CDF Run II
24 data set, which corresponds to more than doubling the candidate event sample. In addition
25 to the larger data set, we investigate in more detail a number of additional systematic
26 effects. As a result of these studies, improved calibrations of detector response and modeling
27 of instrumental backgrounds are used, yielding better agreement between data and SM
28 expectations as obtained from Monte Carlo (MC) event generators. By incorporating these
29 improved models, we perform a search for an excess of events over SM expectations in the
30 dijet mass spectrum equivalent to the search described in Ref. [4].

31 The paper is structured as follows. In Sec. II we describe the CDF II detector and the
32 reconstruction of the final-state particles. In Sec. III we describe the independent energy
33 corrections for simulated quark and gluon jets. In Sec. IV we describe the candidate event
34 selection and the expected composition of the sample. The background modeling is described
35 in Sec. V. The fitting method used in the analysis is described in Sec. VIA, and the results
36 are given in Sec. VIB. We discuss the conclusions in Sec. VII.

37 More information about the studies reported in this paper can be found in Ref. [9].

38 II. EVENT DETECTION AND RECONSTRUCTION

39 Details on the CDF II detector and the event reconstruction are described elsewhere [10].
 40 The detector is cylindrically symmetric around the z direction, which is oriented along the
 41 proton beam axis. The polar angle, θ , is measured from the origin of the coordinate system
 42 at the center of the detector with respect to the z axis. Pseudorapidity, transverse energy,
 43 and transverse momentum are defined as $\eta = -\ln \tan(\theta/2)$, $E_T = E \sin \theta$, and $p_T = p \sin \theta$ re-
 44 spectively, where E is the energy measured in a calorimeter tower (or related to an energy
 45 cluster) with centroid at angle θ with respect to the nominal collision point, and p is a
 46 charged-particle momentum. The azimuthal angle is labeled ϕ . Trajectories of charged par-
 47 ticles (tracks) are determined using a tracking system immersed in a 1.4 T magnetic field,
 48 aligned coaxially with the $p\bar{p}$ beams. A silicon microstrip detector provides tracking over the
 49 radial range 1.5 to 28 cm. A 3.1 m long open-cell drift chamber, the Central Outer Tracker
 50 (COT), covers the radial range from 40 to 137 cm and provides up to 96 measurements.
 51 Sense wires are arranged in eight alternating axial and $\pm 2^\circ$ stereo “superlayers” with 12
 52 wires each. The fiducial region of the silicon detector extends to $|\eta| \approx 2$, while the COT
 53 provides full coverage for $|\eta| \lesssim 1$. The momentum resolution for charged particles in the
 54 COT is $\delta p_T/p_T^2 \approx 0.0015$, where p_T is in units of GeV/ c . The central and plug calorimeters,
 55 which cover the pseudorapidity regions of $|\eta| < 1.1$ and $1.1 < |\eta| < 3.6$ respectively, are
 56 divided into a front electromagnetic and a rear hadronic compartment, which surround the
 57 tracking system in a projective-tower geometry. Muons with $|\eta| < 1$ are detected by drift
 58 chambers and scintillation counters located outside the hadronic calorimeters.

59 Contiguous groups of calorimeter towers with signals exceeding a preset minimum are
 60 identified and summed together into energy clusters. An electron candidate, referred to as a
 61 “tight central electron”, is identified in the central electromagnetic calorimeter as an isolated,
 62 mostly electromagnetic cluster matched to a reconstructed track in the pseudorapidity range
 63 $|\eta| < 1.1$. The electron transverse energy is reconstructed from the electromagnetic cluster
 64 with an uncertainty $\sigma(E_T)/E_T \approx 13.5\%/\sqrt{E_T \text{ (GeV)}} \oplus 1.5\%$.

65 A hadron jet is identified as a cluster of calorimeter energies contained within a cone of
 66 radius $\Delta R \equiv \sqrt{(\Delta\phi)^2 + (\Delta\eta)^2} = 0.4$, where $\Delta\eta$ and $\Delta\phi$ are the distances in pseudorapidity
 67 and azimuthal angle between a tower center and the cluster axis. Jet energies are corrected
 68 for a number of effects that bias the measurement [11]. These corrections include imposing

69 uniformity of calorimeter response as a function of $|\eta|$, removing expected contributions from
70 multiple $p\bar{p}$ interactions per bunch crossing, and accounting for nonlinear response of the
71 calorimeters. These corrections are applied generically to all reconstructed jets independent
72 of the flavor of the associated parton, which is responsible for initiating the particle shower.
73 Recent studies demonstrate the need for additional corrections to the reconstructed energies
74 of jets in simulated events dependent on the flavor of the initiating parton in order to
75 correctly model the observed energy scale of reconstructed jets in data [12]. These additional
76 corrections, applied in the analysis described here, are discussed in greater detail in Sec. III.

77 Muons are identified in three independent subdetectors. Muons with $|\eta| \leq 0.6$ and
78 $p_T > 1.4$ GeV/ c are detected in four layers of planar drift chambers (CMU) located outside
79 the central calorimeter at five interaction lengths. Muons with $|\eta| \leq 0.6$ and $p_T > 2.8$ GeV/ c
80 are detected in four additional layers of drift chambers (CMP) located at eight interaction
81 lengths of calorimeter and steel absorber. Muons with $0.6 \leq |\eta| \leq 1.0$ and $p_T > 2.2$ GeV/ c
82 are detected by a system of eight layers of drift chambers and scintillation counters (CMX)
83 located outside the calorimeter at six to ten absorption lengths. Muon candidates are
84 identified by extrapolating isolated tracks to track segments in the muon detector systems.

85 Missing transverse energy (\cancel{E}_T) is defined as the magnitude of the vector sum of all
86 calorimeter-tower energy depositions projected on the transverse plane. It is used as a
87 measure of the sum of the transverse momenta of the particles that escape detection, most
88 notably neutrinos. The vector sum includes corrected jet energies and also the momenta
89 of high- p_T muon candidates, which deposit only a small fraction of their energy in the
90 calorimeter.

91 III. QUARK AND GLUON ENERGY SCALE MODELING

92 The modeling of calorimeter response to particle showers originating from quarks and
93 gluons is dependent on the different fragmentation and hadronization models used in the
94 simulation for each. Hence, the level of agreement between the simulated and observed
95 energy scales of jets originating from quarks and gluons can differ significantly. We derive
96 specific corrections for the calorimeter response to quark and gluon jets in simulated events
97 using two independent samples of jets with different quark fraction. We use one sample
98 where a jet is emitted in an opposite direction with respect to an energetic photon in the

99 transverse plane, and another sample of $Z \rightarrow \ell^+ \ell^- + \text{jet}$ events (ℓ being an electron or
 100 muon). The former sample is richer in quark jets, the latter in gluon jets. Photon and Z -
 101 boson energies are measured more accurately than jet energies and can be used to calibrate
 102 the jet energy as described below. The criteria for selecting events with a photon or Z boson
 103 associated with only one jet are described in Ref. [12].

104 We derive independent corrections for the quark and gluon jet-energy scales in data and
 105 simulation through Z +jet and γ +jet samples. We define the jet-balance in Z +jet or γ +jet
 106 events as follows:

$$K_{Z,\gamma} = (E_T^{\text{jet}}/p_T^{Z,\gamma}) - 1. \quad (1)$$

107 The measured average balance is corrected with a jet-energy correction factor of $1/(K_{Z,\gamma}+1)$.

108 The jet balance in Eq. (1) can be rewritten as the weighted average of the balance variables
 109 for quark and gluon jets, K_q and K_g respectively. If $F_X^{q,g}$ is the quark, or gluon fraction in
 110 sample X , then we write

$$K_Z = F_Z^q K_q + F_Z^g K_g = F_Z^q K_q + (1 - F_Z^q) K_g \quad (2)$$

111

$$K_\gamma = F_\gamma^q K_q + F_\gamma^g K_g = F_\gamma^q K_q + (1 - F_\gamma^q) K_g, \quad (3)$$

112 or, solving for K_q and K_g ,

$$K_q = \frac{1}{F_\gamma^q - F_Z^q} [(1 - F_Z^q) K_\gamma - (1 - F_\gamma^q) K_Z] \quad (4)$$

113

$$K_g = \frac{1}{F_\gamma^g - F_Z^g} [F_\gamma^q K_Z - F_Z^q K_\gamma]. \quad (5)$$

114 These equations apply separately to data and MC simulation with distinct balance factors
 115 K_X^{d} and K_X^{MC} and can include a dependence on the energy of the jet, $F_X^q \rightarrow F_X^q(E_T^{\text{jet}})$
 116 and $K_X \rightarrow K_X(E_T^{\text{jet}})$.

117 In order to solve for K_q and K_g , we need to input the values of $K_{Z,\gamma}$ and $F_{Z,\gamma}^q$. We extract
 118 the former in data and simulation by constructing the balancing distribution, as defined in
 119 Eq. (1), in bins of E_T^{jet} , and fitting the core of the distribution around its maximum with
 120 a Gaussian function. We determine $F_{Z,\gamma}^q$ in simulation by matching jets to their originating
 121 partons, by requiring $\Delta R < 0.4$ between the parton and the jet. In the γ +jet balancing
 122 sample the quark fraction is about 85% at $E_T^{\text{jet}} \approx 30$ GeV, and reduces to about 71% at

123 $E_T^{\text{jet}} \approx 70$ GeV. In the Z +jet balancing sample this fraction is about 38% and 49% in the
 124 same E_T^{jet} ranges. In data, it is not possible to match jets to their originating parton, and
 125 we rely on the values of $F_{Z,\gamma}^q(E_T^{\text{jet}})$ extracted from the simulated samples.

126 Using Eqs. (4)-(5), we derive K_q and K_g in data and simulation as functions of jet
 127 E_T . Rather than correcting both data and simulation, the factors K_q and K_g are used
 128 to determine the corrections to simulated jets, in order to best match the energy scale
 129 observed in data. These corrections are defined as $(K_q^{\text{d}} + 1)/(K_q^{\text{MC}} + 1)$ for quark jets and
 130 $(K_g^{\text{d}} + 1)/(K_g^{\text{MC}} + 1)$ for gluon jets, the extracted values for which are shown in Fig. 1.

131 The transverse energy threshold of the photon online event-selection (trigger) is 25 GeV
 132 [13], so reliable balancing information is not available for jets with energies less than 27.5
 133 GeV in the photon-triggered sample. Since we are interested in jets with energies extending
 134 down to 20 GeV, we extrapolate the quark-jet-energy corrections to lower jet energies, and
 135 use the Z +jet balancing sample to extract a gluon correction assuming this extrapolated
 136 quark correction.

137 As both the quark and gluon corrections do not depend on jet energy for jets with
 138 $E_T \geq 15$ GeV, we fit them to a constant. To better match the data, quark-jet energies in the
 139 simulation should be increased by $(1.4 \pm 2.7)\%$, while gluon-jet energies should be decreased
 140 by $(7.9 \pm 4.4)\%$. The reported uncertainties are the sum in quadrature of the statistical and
 141 systematic contributions. The systematic sources are dominated by a 10% uncertainty on
 142 the quark fractions in the Z +jet or γ +jet balancing samples. The uncertainty is estimated
 143 by fitting the data distribution of a quark-gluon discriminant parameter [12] with quark
 144 and gluon templates from simulation. The average deviation of the extracted quark fraction
 145 from the prediction is taken as the systematic uncertainty on the quark fraction. Other
 146 sources of systematic uncertainties include the extrapolation to low quark-jet energy and
 147 the differences between the allowed number of interaction vertices in the Z +jet and γ +jet
 148 samples. The sizes of statistical and systematic uncertainties are comparable. Because of
 149 the default corrections applied to reconstructed jet energies, which are designed to equate
 150 the energy scales for simulated and observed jets on average, uncertainties on the additional,
 151 independent corrections derived for quark and gluon jets are necessarily anticorrelated with
 152 one another. Combination of these two anticorrelated uncertainties encompasses the un-
 153 certainty on the absolute energy scale for generic jets, which is the dominant uncertainty
 154 assigned to the default CDF jet-energy corrections. In order to avoid double-counting, only

155 the anticorrelated uncertainties associated with the additional quark and gluon corrections
 156 are applied within this analysis. The observation that the additional energy-scale correction
 157 for quark jets is consistent with unity within measurement uncertainties is consistent with the
 158 *in situ* calibration of light-quark jet energies performed in conjunction with the top-quark
 159 mass measurement [14].

160 Similar studies in the Z +jet balancing sample show that the calorimeter responses to
 161 heavy-flavor quark jets in simulation and data agree. Since the uncertainty on the energy
 162 scale of heavy-quark jets relative to that of light-quark jets is roughly 1% [15], possible
 163 discrepancies of the calorimeter responses to heavy-flavor quark jets in simulation and data
 164 are expected to be covered by the light-quark jet-energy-scale uncertainty.

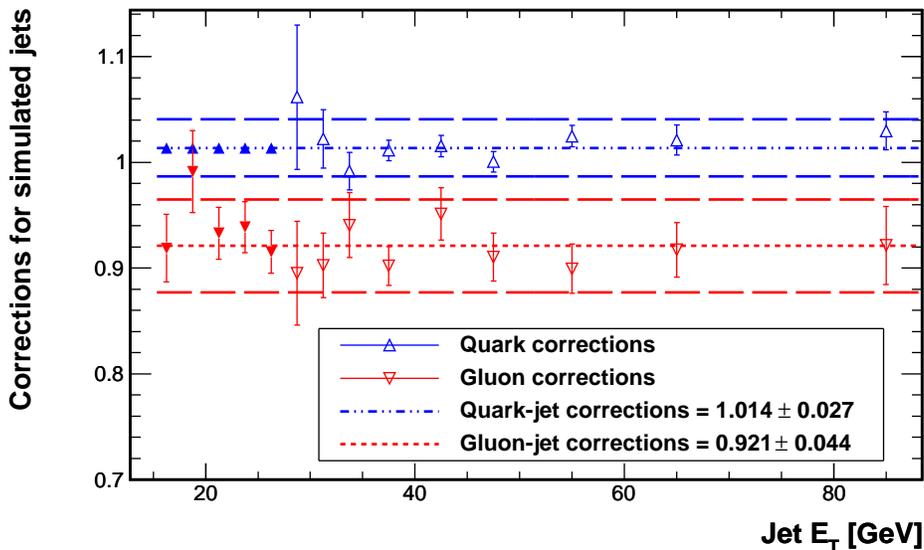

FIG. 1. Derived energy scale corrections for simulated quark jets and gluon jets as a function of jet E_T . The open triangles represent corrections derived jointly from the γ +jet and Z +jet balancing samples, while the filled triangles in the low-jet E_T region are obtained from the Z +jet sample only, assuming a constant correction for the quark jet-energy scale. Error bars are from statistical sources only. The short dashed lines show the fits to constant energy corrections, and the long dashed lines represent the total systematic uncertainty bands on the correction determined by the fit.

165 IV. DATA SET AND EVENT SELECTION

166 We select a sample enriched in W +jets events by requiring a large transverse-momentum
167 electron or muon passing the high- p_T lepton trigger requirements, large missing transverse
168 energy, and two energetic jets. The full CDF Run II data set is used, corresponding to an
169 integrated luminosity of 8.9 fb^{-1} .

170 A. Online event selection

171 The trigger is a three-level event filter with tracking information available at the first level.
172 The first level of the central-electron trigger requires a charged particle with $p_T > 8 \text{ GeV}/c$
173 pointing to a calorimeter tower with $E_T^{EM} > 8 \text{ GeV}$ and $E^{HAD}/E^{EM} < 0.125$, where E^{HAD} ,
174 E^{EM} are the energy deposited by the candidate electron in the hadronic and electromagnetic
175 calorimeters respectively. The first level of the muon trigger requires a charged particle with
176 $p_T > 4 \text{ GeV}/c$ or $8 \text{ GeV}/c$ pointing to a muon stub. Full lepton reconstruction (Sec. II) is
177 performed at the third trigger level, with requirements of $E_T > 18 \text{ GeV}$ for central electrons
178 and $p_T > 18 \text{ GeV}/c$ for muons.

179 B. Offline event selection

180 Offline, we select events containing exactly one electron with $E_T > 20 \text{ GeV}$ or muon with
181 $p_T > 20 \text{ GeV}/c$, large missing transverse energy ($\cancel{E}_T > 25 \text{ GeV}$), and exactly two jets with
182 $E_T > 30 \text{ GeV}$ and $|\eta| < 2.4$. In order to select events with W bosons and to reject multijet
183 backgrounds, we impose the following requirements: transverse mass $m_T > 30 \text{ GeV}$, where
184 $m_T = \sqrt{2p_T^\ell \cancel{E}_T \{1 - \cos[\Delta\phi(\vec{p}_T^\ell, \vec{\cancel{E}}_T)]\}}$, ℓ being an electron or a muon; azimuthal angle be-
185 tween \cancel{E}_T and the most energetic jet $\Delta\phi(\cancel{E}_T, j_1) > 0.4$; difference in pseudorapidity between
186 the two jets $|\Delta\eta(j_1, j_2)| < 2.5$; and transverse momentum of the dijet system $p_T^{jj} > 40 \text{ GeV}/c$.
187 The position of the primary interaction is found by fitting a subset of well-measured tracks
188 pointing to the beam line and is required to lie within 60 cm from the center of the detector.
189 If multiple vertices are reconstructed, the vertex associated with charged particles yielding
190 the maximum scalar sum p_T is defined as the primary-interaction point. The longitudinal
191 coordinate z_0 of the lepton track at the point of closest approach to the beam line must also

192 lie within 5 cm of the primary-interaction point.

193 **V. SIGNAL AND BACKGROUND MODELING**

194 We search for an excess of events in the invariant-mass spectrum of the two reconstructed
195 jets from the decay of a potential non-SM particle. To be consistent with Ref. [4], we model
196 the excess with a Gaussian function centered at a mass of $144 \text{ GeV}/c^2$ with a width of 14.3
197 GeV/c^2 , determined by the calorimeter resolution expected from simulation.

198 There are two main categories of background processes: physics processes, such as the
199 dominant W +jets mechanism, where all final-state particles are correctly identified, and
200 instrumental background, where the lepton is misidentified and the missing transverse energy
201 is mismeasured. The expected rates of the major backgrounds for a $20\text{-}300 \text{ GeV}/c^2$ dijet-
202 mass range are reported in Table I, as obtained from the modeling of each background
203 described below.

204 **A. Physics backgrounds: W/Z +jets, top-quark, and diboson production**

205 The dominant contributing process to the selected sample is the associated production
206 of W bosons and jets. Another process with a non-zero contribution to the selected sample
207 is Z +jets, where a lepton from the Z -boson decay is not detected. The predicted ratio
208 between number of events with heavy-flavor and light-flavor jets in W/Z +jets processes is
209 about 10%. To study the effects of W +jets and Z +jets processes, events are generated
210 using ALPGEN [20] interfaced with PYTHIA [21] for parton showering and hadronization.
211 Because of large uncertainties associated with the NLO calculations [22], the magnitude of
212 W +jets and Z +jets contributions is obtained from a fit to the data, where the ratio of the
213 W +jets cross section to Z +jets cross sections is constrained to 3.5 as predicted by theory.
214 Top-quark pair production is modeled with events simulated using PYTHIA and assuming
215 a top-quark mass of $172.5 \text{ GeV}/c^2$. The magnitude of the simulated top-pair contribution
216 is normalized based on the latest CDF measurement on an independent sample with one
217 identified lepton, significant transverse momentum imbalance, and at least three jets [16].
218 The uncertainty of the top-quark pair cross section is 7%. Processes producing a single
219 top quark are modeled by the MADEVENT event generator [23] interfaced to PYTHIA for

TABLE I. Expected number of events in the 20-300 GeV/ c^2 dijet-mass range with electron and muon candidates in the selected sample from each of the background processes. The total expected number of events is constrained to be equal to the number of observed events, as described in Sec. V B. The reported uncertainties and the central values for the W/Z +jets contributions are obtained from the \cancel{E}_T fit (Sec. V B). The uncertainties on the top-quark-pair contribution are derived from the experimental measurement [16], those on the single-top-quark and diboson contributions come from the theoretical cross sections [17, 18, 19]. The central value and the uncertainty for the QCD multijet process is obtained from the \cancel{E}_T fit (Sec. V B).

Production process	Events (electron channel)	Events (muon channel)
W +jets	8900 ± 119	5959 ± 95
Z +jets	248 ± 3	472 ± 9
$t\bar{t}$	670 ± 44	431 ± 28
Single-top	161 ± 10	106 ± 7
Diboson	589 ± 36	392 ± 24
QCD multijets	898 ± 127	20 ± 3
Total expected	11466 ± 185	7380 ± 109

220 showering and hadronization. The cross sections are normalized to the next-to-next-leading
 221 order (NNLO) plus next-to-next leading log (NNLL) for the s -channel [17] and next-to-
 222 next-to-next-leading order (NNNLO) plus next-to-leading log (NLL) for the t -channel [18]
 223 theoretical calculations, with uncertainties of 11%.

224 Diboson (WW , WZ , ZZ) production is modeled with PYTHIA. Expected diboson con-
 225 tributions are normalized based on the theoretical NLO cross sections [19]. The resulting
 226 uncertainty on the diboson contribution is roughly 6%.

227 The remaining background process is multijet production, where one jet mimics the
 228 experimental signature of a lepton and a mismeasurement in the calorimeter leads to spurious
 229 \cancel{E}_T in the event. We use data to model this contribution, as described in Sec. V B.

230 Other sources of systematic uncertainties that affect the background normalizations are
 231 those associated with the luminosity measurement (6%) [26], effects of initial-state and final-
 232 state radiation (2.5%), modeling of the parton distribution functions (2.2%), modeling of the

233 jet-energy scale (2.7% for quark jets and 4.4% for gluon jets with a 100% anticorrelation),
 234 modeling of the jet-energy resolution (0.7%), and modeling of the trigger efficiency (2.2%).
 235 In addition to uncertainties on the expected contributions from each background process, we
 236 also consider systematic uncertainties that affect the shape of the invariant-mass distribution
 237 for each process. The most important are the uncertainties on the jet-energy scale and on
 238 the renormalization and factorization scales in the $W + \text{jets}$ process, which are taken to be
 239 equal. For modeling the former, two alternative invariant-mass distributions are obtained
 240 by varying the jet-energy scale within its expected $\pm 1\sigma$ uncertainty. For the latter, the
 241 factorization scale used in the event generation [27] is doubled and halved in order to obtain
 242 two alternative shapes. As an example, the relative difference between the varied and
 243 nominal shapes for the dominant background process ($W + \text{jets}$) due to the jet-energy-scale
 variation is shown in Fig. 2.

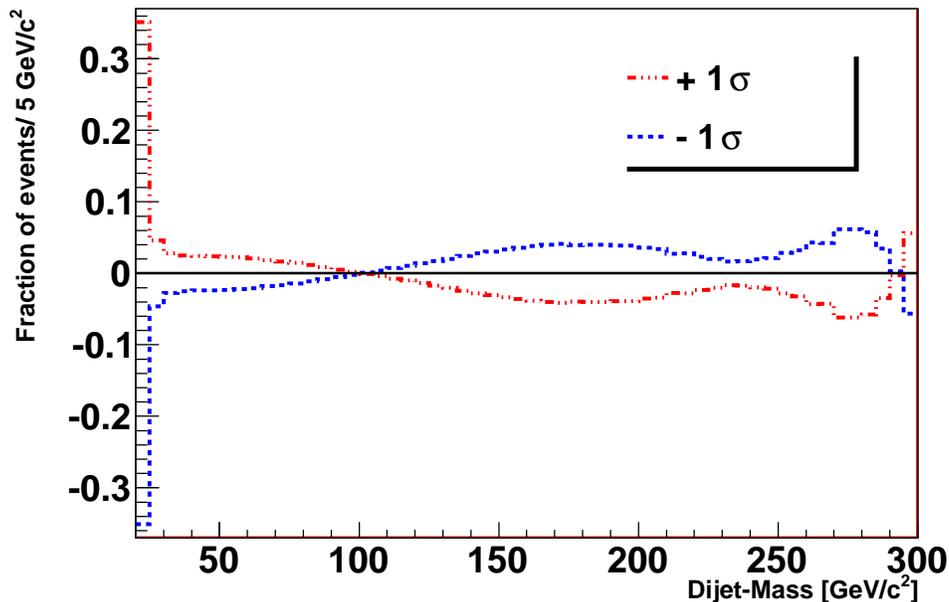

FIG. 2. Relative difference in the combined electron and muon samples between the nominal dijet mass distribution and the one obtained by varying the jet-energy scale by $\pm 1\sigma$ in $W + \text{jets}$ events.

245 B. Multijet production

246 Multijet events can be identified as signal candidates when one of the jets is misidentified
247 as a lepton. This mismeasurement can also result in significant missing transverse energy.
248 Because it is unlikely for a jet to deposit energy in the muon detectors, the misidentification
249 probability of a muon is lower than that of an electron. The multijet-background contribu-
250 tion is thus negligible in the muon channel ($< 0.5\%$), while it is close to 10% in the electron
251 channel (Table I). Therefore, we concentrate on discussing the multijet-background model-
252 ing for events with electron candidates. Similar methods are used to model this background
253 for muon events.

254 To model the multijet-background distribution, we use an event sample obtained from
255 the same selection as described in Sec. II except that two identification criteria for the
256 electron candidates that do not depend on the kinematic of the event (*e.g.*, the fraction of
257 energy in the hadronic calorimeter) are inverted [24]. The particles identified with those
258 inverted requirements are referred to as “nonelectrons”. This ensures that the sample used
259 for modeling the multijet background is statistically independent of the signal sample, while
260 as similar as possible kinematically. Nevertheless, several tunings are needed to this sample
261 in order to adequately model the multijet component in the signal sample. First, there is
262 a small contribution of events with prompt leptons from boson decays. We subtract this
263 contribution bin-by-bin for any variable of interest using the theoretical prediction for that
264 bin. A second tuning of the nonelectron sample accounts for the trigger bias. The trigger
265 selects events based on the E_T of the reconstructed electron or nonelectron candidate, but
266 the event kinematic properties are determined by the E_T of the corresponding jet. We define
267 this jet as the jet with $\Delta R < 0.4$ with respect to the (non)electron. To properly model the
268 event kinematics properties, the energy distribution of this jet should be the same in events
269 with misidentified electron and nonelectron candidates. We define a control region enriched
270 in multijet events, selected with the same criteria as for the signal region, except for the
271 requirement of $\cancel{E}_T < 20$ GeV or $m_T < 30$ GeV. The estimated fraction of multijet events in
272 this region is 84%. When comparing the energy distribution of jets matched to misidentified
273 electrons with jets matched to nonelectrons in this control region, we find discrepancies
274 due to the trigger on electron E_T (Fig. 3). The jets matched to misidentified electrons
275 have a higher fraction of their measured energy in the electromagnetic calorimeter than

jets matched to nonelectrons; therefore, in order to have a nonelectron of the same energy
 as a corresponding misidentified electron, the energy of the jet producing the nonelectron
 must be higher. The trigger threshold thus leads to a higher average E_T of jets producing
 nonelectrons than of jets producing misidentified electrons. To remove this trigger bias,
 we reweight events in the nonelectron sample such that the energy spectrum of the jets
 matched to misidentified electrons is equivalent to the energy spectrum of jets matched to
 nonelectrons. The reweighting is obtained from the control region and the same weights are
 used in the signal region.

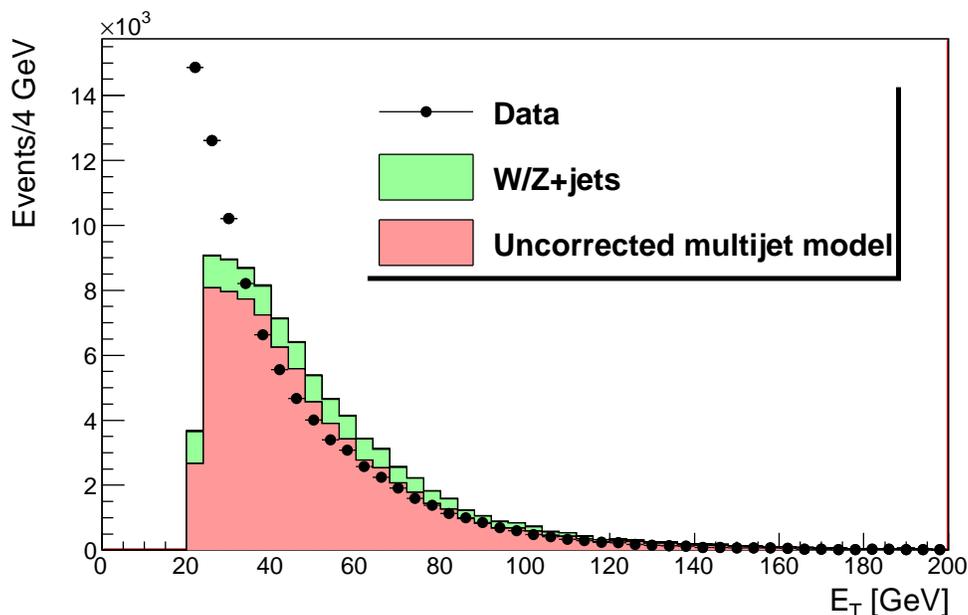

FIG. 3. Transverse-energy distribution of jets matched to identified electrons in the multijet-enriched control region in data (circles), uncorrected multijets model (dark shaded histogram), and W/Z +jets simulation (light shaded histogram). The magnitude of W/Z +jets contributions is normalized to the NLO calculations [22], while the magnitude of the multijet model is obtained from the data. In subsequent analysis, the multijet model is reweighted such that the predicted and observed energy spectra agree.

A final tuning of the nonelectron sample addresses the difference in jet-energy scale
 between the jet producing the nonelectron and the jet producing a misidentified electron.
 We investigate this difference using PYTHIA QCD dijet events. For the same primary parton
 energy, the energy of jets matched to nonelectrons is systematically lower than the energy of

288 jets matched to identified electrons. Based on the observed differences, we derive an energy
 289 correction factor as a function of the initial jet-energy, which is applied to events in the
 290 nonelectron sample.

291 In order to test the tunings, we use the multijet-enriched control region. An important
 292 kinematic distribution related to the dijet-invariant mass is the p_T of the two-jet system.
 293 Figure 4 shows the improvement in the modeling of this variable after all tunings are applied
 294 and is indicative of the improvement seen in other relevant kinematic variables.

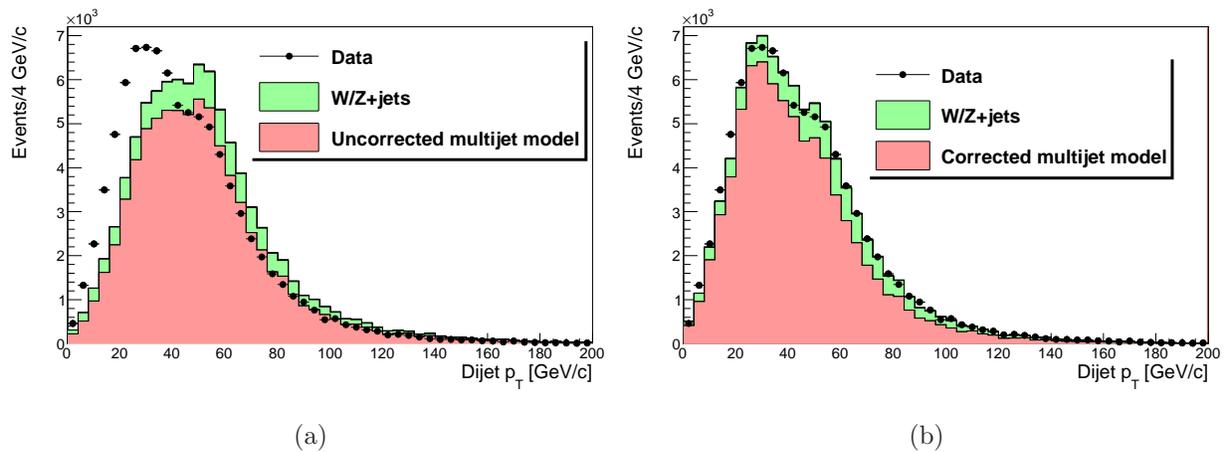

FIG. 4. Transverse-momentum distribution of the two-jet system in the multijet-enriched control sample as observed in the data (circles) and as predicted by the W/Z +jets simulation (light shaded histogram) and the nonelectron-based model (dark shaded histogram) before (a) and after (b) application of tunings to the nonelectron-based multijet model. The magnitude of W/Z +jets contributions is normalized to the NLO calculations [22], while the magnitude of the multijet model is obtained from the data.

295 We also investigate the impact of the tunings applied to the nonelectron-based multijet
 296 model on the signal sample, defined in Sec. IV. To increase the statistical accuracy of the
 297 sample, we loosen the selection by removing the two-jet system p_T requirement and lowering
 298 the E_T requirements to 25 GeV. The resulting improvement in the modeling of the two-jet
 299 system p_T distribution in this sample is shown in Fig. 5.

300 The contribution of the multijet background to the selected sample is determined using
 301 a three-component fit to the \cancel{E}_T distribution in the data. The three components are the
 302 multijet background, the W/Z +jets production, and the other electroweak processes (top-

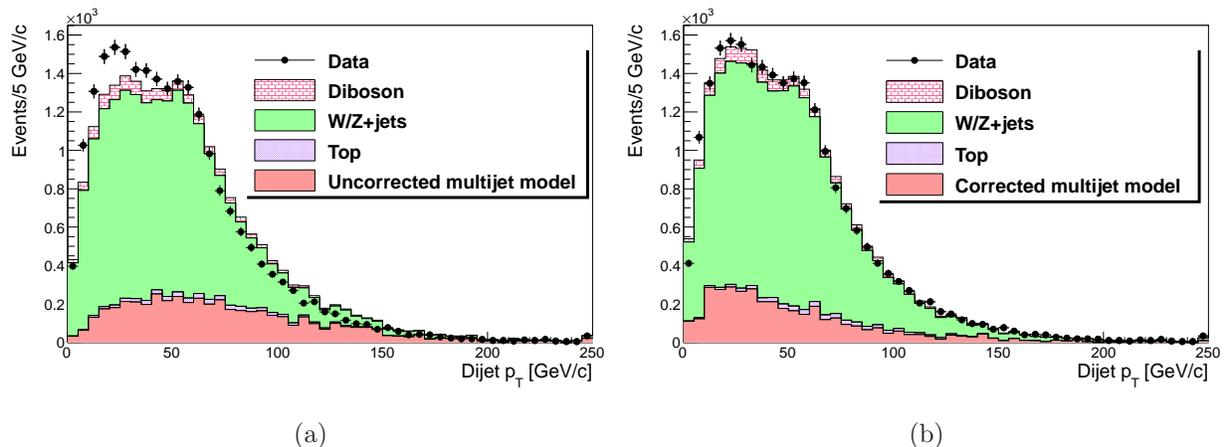

FIG. 5. Transverse-momentum distribution of the two-jet system in the selected event sample with looser selection criteria as observed in the data and as predicted by the models before (a) and after (b) application of tunings to the nonelectron-based multijet model.

303 quark and diboson production). The last component is constrained to theoretical predictions,
 304 whereas the magnitudes of the W/Z +jets and the multijet contributions are allowed to float
 305 in the fit. The results are shown in Fig. 6. We estimate the amount of multijet background in
 306 the electron and muon sample to be $(7.8 \pm 0.2)\%$ and $(0.27 \pm 0.01)\%$ respectively, where the
 307 uncertainties are statistical only. We consider several systematic uncertainties: jet-energy-
 308 scale modeling (0.9%), choice of the fit variable (13.1%), disagreement between the observed
 309 and predicted multijet \cancel{E}_T distribution (4.4%), and theoretical uncertainties on the cross
 310 sections (0.9%). The total systematic uncertainty on the multijet background estimate is
 311 14.0%.

312 VI. FIT AND RESULTS

313 We first describe the procedure used to fit the observed dijet-mass distribution in data,
 314 including contributions from background and an hypothetical signal. We then present two
 315 sets of results. For the first set, we do not incorporate the specific jet-energy-scale correc-
 316 tions for quark and gluon jets nor the tuning of the multijet-background model, essentially
 317 performing the analysis of Ref. [4] on the full CDF Run II data set. The final results are
 318 then given, which include those obtained when the improvements are incorporated.

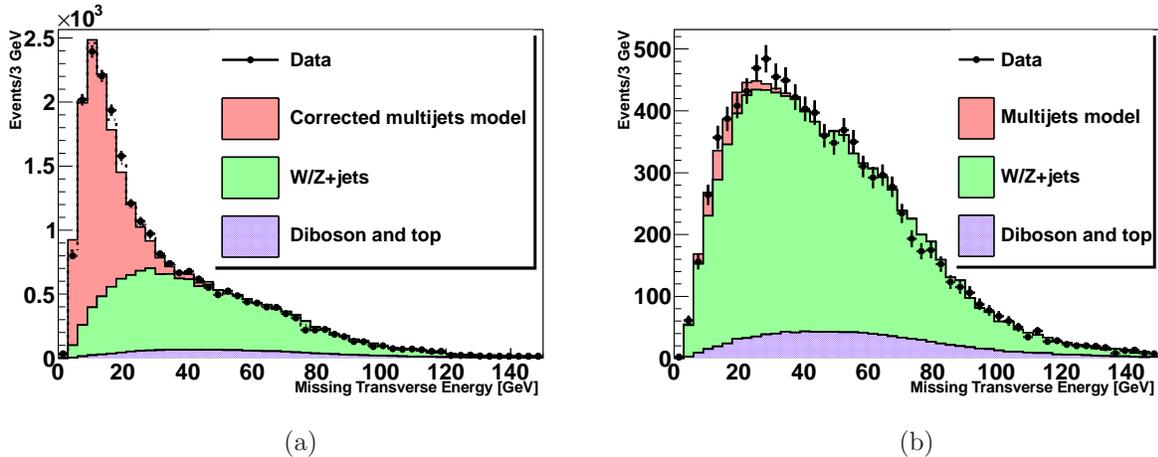

FIG. 6. Missing transverse-energy distribution for events containing electrons (a) and muons (b) from the selected sample. The distributions of observed data are shown with fit background overlaid.

319 A. Fit technique

320 Uncertainties on the predictions are parametrized with nuisance parameters, and the data
 321 are used to constrain both the signal size and the values of these parameters.

322 We use the following approach to set an upper limit on the production rate of a hypo-
 323 theoretical new particle. We maximize a binned likelihood function $L(\text{data}|\vec{\theta}, \vec{\nu})\pi(\vec{\nu})$, which
 324 expresses the probability of observing the data given the model parameters $\vec{\theta}$ and the nui-
 325 sance parameters $\vec{\nu}$. The likelihood is a product of Poisson probabilities for the observed
 326 data in each bin. The function $\pi(\vec{\nu})$ is a product of Gaussian constraints, one for each
 327 systematic uncertainty (treated as nuisance parameters in the fit), which incorporates ex-
 328 ternal information about the parameter, as measured in control samples or obtained from
 329 other sources. The nuisance parameters describe three classes of systematic uncertainties:
 330 bin-by-bin uncertainties, which are considered uncorrelated between individual bins of each
 331 predicted distribution; shape uncertainties, which correspond to coherent distortions across
 332 the bins of a distribution, parametrized by a single nuisance parameter; and rate uncertain-
 333 ties, which coherently affect the normalization of all bins within one distribution. Rate and
 334 shape uncertainties may be correlated. For example, modifications of the jet-energy-scale
 335 shift the mass of a resonance to higher or lower values (Fig. 2); in addition, they affect the

336 magnitude of the predicted contribution of the process due to the selection criterion that jets
 337 pass a minimum E_T threshold. These correlations are taken into account by allowing each
 338 source of systematic uncertainty to affect both rates and shapes of multiple distributions. A
 339 detailed description of the likelihood function is given in Ref. [24]. Restrictions are placed
 340 on the allowed ranges of the nuisance parameters to ensure that all event-yield predictions
 341 are non-negative.

342 **B. Results**

343 To reproduce the previous analysis [4], a first fit to the dijet invariant-mass spectrum is
 344 performed without incorporating the improvements described in the previous sections. In
 345 addition to the SM contributions, an additional Gaussian component centered at $144 \text{ GeV}/c^2$
 346 with a width of $14.3 \text{ GeV}/c^2$ is incorporated in the fit to model a potential non-SM contri-
 347 bution. The result of the fit in the full electron and muon data sample is shown in Fig. 7: an
 348 excess of events over the background prediction is observed in the signal region, similar to
 349 what observed in Ref. [4]. Assuming that this new contribution has the same acceptance as
 350 that for a $140 \text{ GeV}/c^2$ Higgs boson produced in association with a W boson, the extracted
 351 cross section is $2.4 \pm 0.6 \text{ pb}$. Assuming only SM processes, the probability to measure a
 352 value as large or larger than the observed cross section is 2.6×10^{-5} , which corresponds
 353 to 4.2σ in terms of standard deviations. The excess is similar in the electron and muon
 354 channels, as shown in Fig. 8.

355 Figure 9 shows that the SM predictions do not model properly the region at low ΔR
 356 between the two jets ($\Delta R(j_1, j_2)$) in the muon sample. A similar discrepancy is observed in
 357 the electron sample. However, jet pairs from heavy particles are expected to be produced
 358 more often at large $\Delta R(j_1, j_2)$. Therefore, applying a $\Delta R(j_1, j_2) > 0.7$ requirement is
 359 not expected to bias heavy-particle searches. Nonetheless, we investigate the effect of this
 360 requirement on the final result. Figures 10-11 show that, although the agreement between
 361 data and SM expectations in the region at low masses is improved, similar discrepancies as
 362 in Figs. 7-8 are present for dijet-invariant masses larger than $50 \text{ GeV}/c^2$. We extract a cross
 363 section $\sigma_{WX} = (2.3 \pm 0.5) \text{ pb}$, which is compatible with the one extracted with no $\Delta R(j_1, j_2)$
 364 restriction.

365 Additional fits incorporate the corrections described in Secs. III and VB. First, jet-

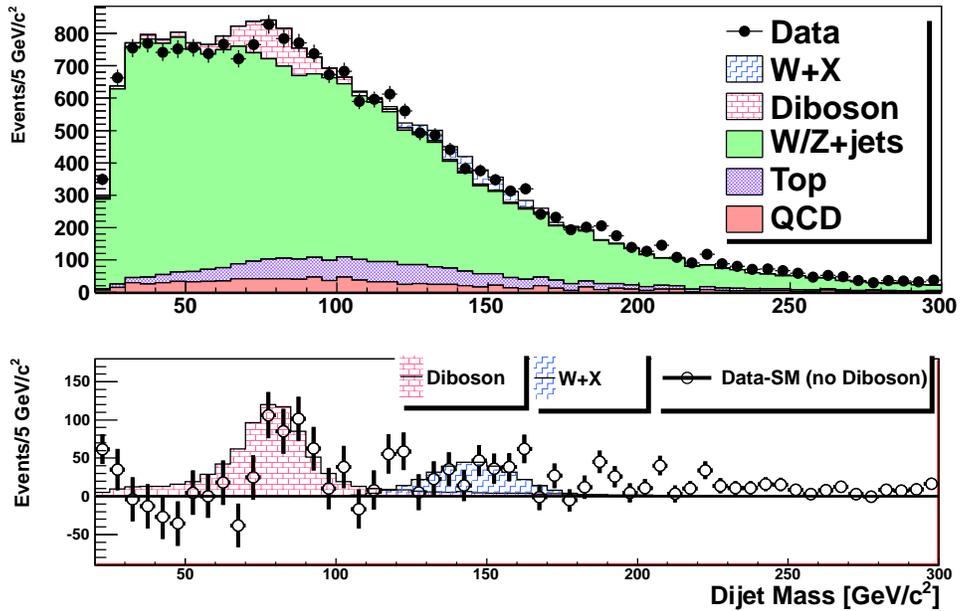

FIG. 7. Dijet mass distribution with fit results overlaid in the combined electron and muon data sets prior to incorporating the improvements discussed in the text, equivalent to updating the analysis described in Ref. [4] on the full CDF data set. The bottom panel shows data with all fit background contributions subtracted except those from diboson production.

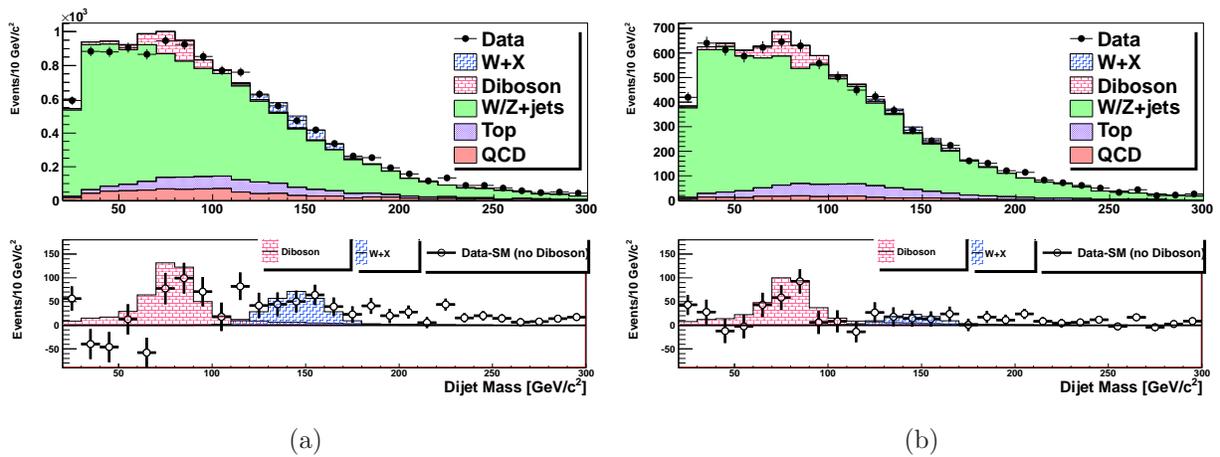

FIG. 8. Same distribution as in Fig. 7, shown separately for the electron (a) and muon (b) samples.

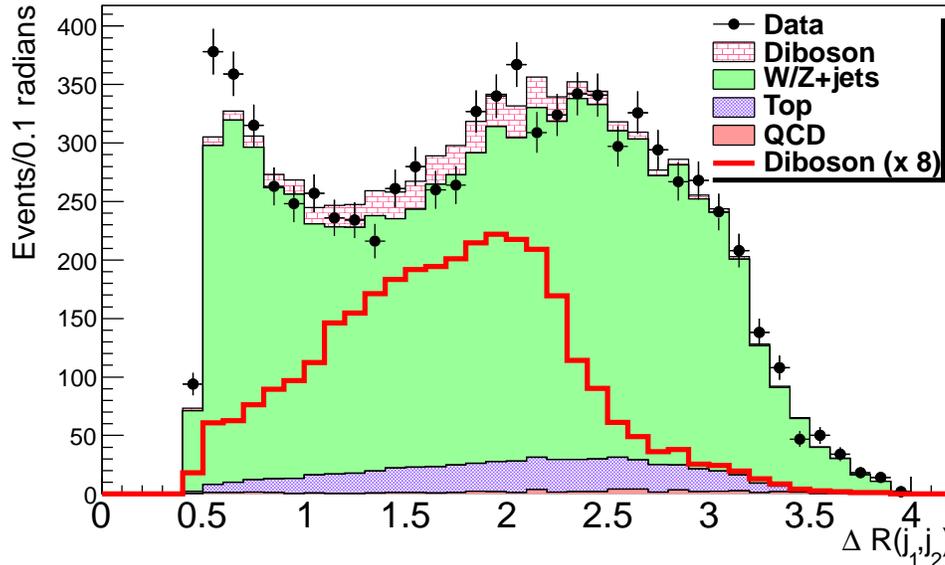

FIG. 9. Distribution $\Delta R(j_1, j_2)$ distributions in the muon sample as observed in the data and as predicted by the models incorporating improved jet-energy-scale corrections for simulated quark and gluon jets. The diboson distribution (red line) magnified by a factor of 8 is also shown as an example of the $\Delta R(j_1, j_2)$ distribution for a heavy-particle decay.

366 energy-scale corrections for simulated quark and gluon jets described in Sec. III are incor-
 367 porated. The resulting fits to the selected-event distributions with electrons and muons are
 368 shown separately in Fig. 12. Good agreement between the observed data and the fit contri-
 369 butions is seen for events with muons, while the agreement is still rather poor for events with
 370 electrons. Final fits performed after incorporating also tunings to the multijet-background
 371 model lead to excellent agreement between the observed electron data and the fit-SM-process
 372 contributions, as shown in Fig. 13. The fit to the muon data, where the multijet background
 373 is very small, is unchanged.

374 The final fit result for the combined electron and muon data is shown in Fig. 14. The
 375 magnitude of SM contributions is normalized to the expected rates given in Table I. Since
 376 the data are consistent with the SM predictions and no significant excess is observed, we
 377 set an upper limit of 0.9 pb at the 95% C.L. on the cross section of a new particle with a
 378 mass of 144 GeV/ c^2 produced in association with a W boson. The limit assumes that the
 379 new resonance has an acceptance equal to that of a Higgs boson produced in association

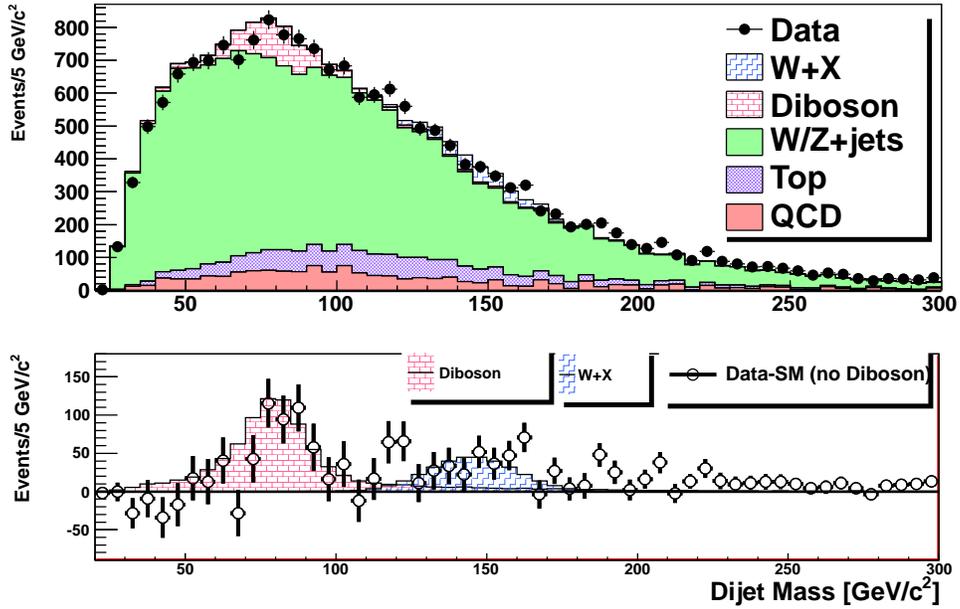

FIG. 10. Dijet mass distribution with fit results overlaid in the combined electron and muon data sets selected by applying an additional $\Delta R(j_1, j_2) > 0.7$ requirement and prior to incorporating the improvements discussed in the text. The bottom panel shows data with all fit background contributions subtracted except those from diboson production.

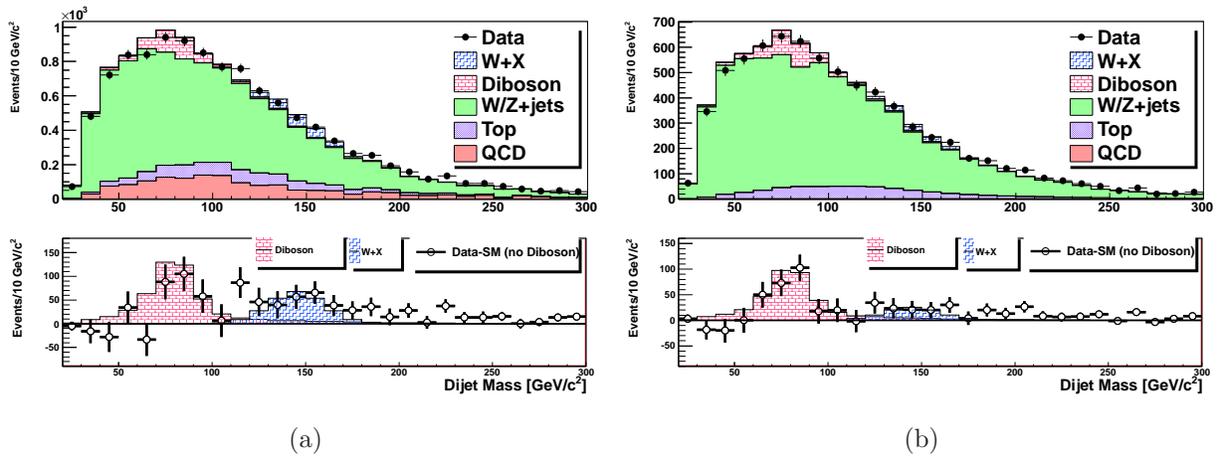

FIG. 11. Same distribution as in Fig. 10, shown separately for the electron (a) and muon (b) samples.

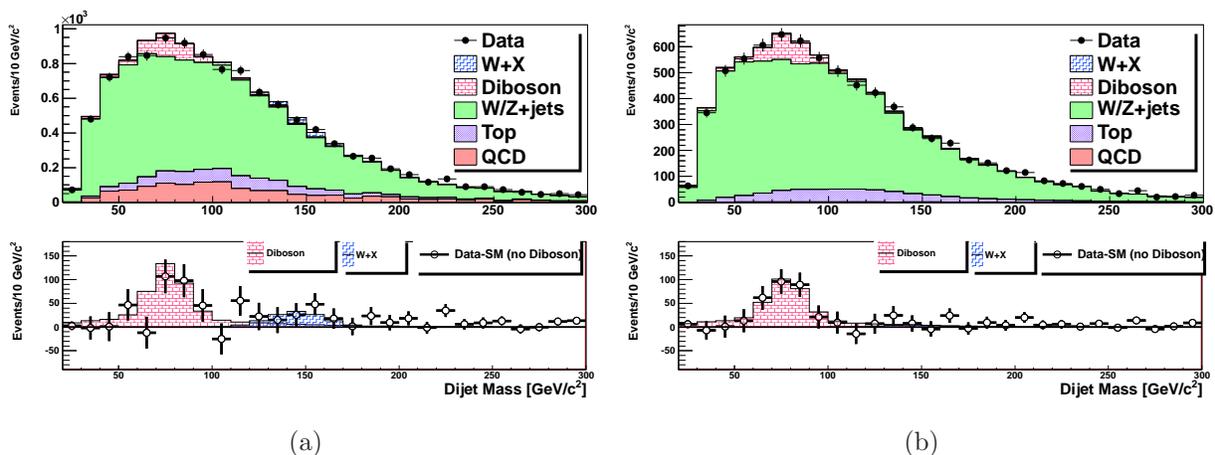

FIG. 12. Dijet mass distribution with fit results overlaid in the electron (a) and muon data sets (b) incorporating improved jet-energy-scale corrections for simulated quark and gluon jets but no tuning on the multijet-background modeling. The bottom panel shows data with all fit background contributions subtracted except those from diboson production.

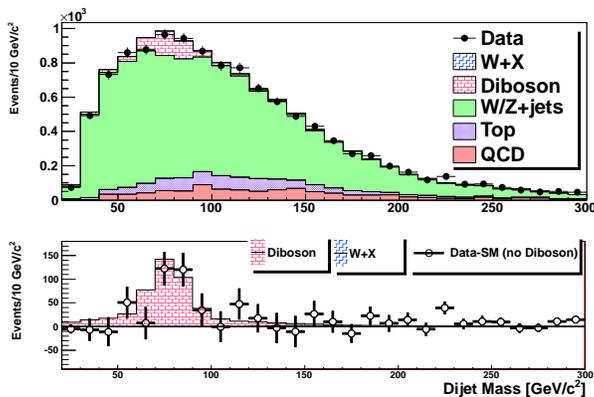

FIG. 13. Dijet mass distribution with fit results overlaid in the electron data set incorporating improved jet-energy-scale corrections for simulated quark and gluon jets and tunings on the multijet-background modeling. The bottom panel shows data with all fit background contributions subtracted except those from diboson production.

380 with a W boson, and the limit is set using likelihood-ratio ordering [25]. When generating
 381 pseudoexperiments we start from the rates in Table I and we allow for variations within
 382 systematic uncertainties mentioned in Sec. V. Shape variations due to the jet-energy-scale,
 383 factorization and normalization scale uncertainties are also considered.

Dijet mass distribution with fit results overlaid in the combined electron and muon data sets incorporating improved jet-energy-scale corrections for simulated quark and gluon jets and tunings on the multijet-background modeling. The bottom panel shows data with all fit background contributions subtracted except those from diboson production.

384 VII. CONCLUSION

385 We present a study of the dijet invariant-mass spectrum in events containing a single
 386 lepton, large missing transverse energy, and exactly two jets. Since the previous publication
 387 [4], additional studies of potential systematic effects have led to the incorporation of specific
 388 jet-energy-scale corrections for simulated quark and gluon jets and tunings of the data-driven
 389 modeling for the multijet-background contributions. The distribution observed in the full
 390 CDF Run II data set is in good agreement with the SM expectations, whose dominant
 391 contributing process is W +jets, which is modeled using ALPGEN event generator combined
 392 with PYTHIA simulation of parton showering and hadronization. A 95% C.L. upper limit of
 393 0.9 pb is set on the cross section times branching ratio for production and decay into dijets
 394 of a new particle with mass of $144 \text{ GeV}/c^2$ in association with a W boson.
